Diarrheic Sitophobia.—Not all the patients who refuse food because of the fear that it will do them harm, suffer from constipation. In a recent case the patient was suffering from diarrhea. The taking of food seemed to give rise to liquid stools in which undigested food material was passed. Gradually the patient limited the amount of food taken so much that he lost weight and his weak anemic condition still further increased the tendency to diarrhea. As a result of sitophobia the first prominent symptom is always anemia. As a result of this, insomnia is apt to develop; there may be even slight febrile movements and there will be usually a small amount of albumin in the urine. The pallor and dizziness with albumin may seem to indicate the existence of nephritis. The best proof that there is no nephritis in the case will come when as a result of increase in the amount of food consumed, the albumin disappears.

Treatment.—The most important indications for the treatment of sitophobia are the persuasion of the patient to take more food. This will sometimes require considerable argument and representation of the necessity of more food than is being taken. When, as is usually the case, there is considerable loss of nervous tone, strychnine is indicated. Where anemia is an important feature of the case, iron will be needed. In cases where constipation exists, the tendency of iron to increase the constipation must not be forgotten and the bowels must be carefully regulated. Drugs alone without regulation of the patient's diet will not bring about improvement.

Syphilis of the Liver.—Dr. Einhorn said that syphilis of the liver is well known and has been well described. It has not been treated from a clinical standpoint, however, quite as much as its importance justifies. The description of it has been left too much to the pathologists and its treatment and symptomatology have been considered rather by the syphilographer. Long ago Ricord described gumma of the liver and pointed out the conditions that develop in this important organ as a consequence of syphilitic affection. To Virchow, however, we owe the scientific pathology of syphilis of the liver and after his descriptions the clinicians established the nosology of the diease. Syphilitic enlargements of the liver occur from three and one-half months to twenty-five years after infection. The enlargement is usually irregular and nodular in character, but this symptom is not invariable. At times considerable tenderness in the hepatic region is a prominent symptom. Spontaneous pain is usually not noted. As a result of interference with the portal circulation, ascites is apt to become a prominent feature of the disease. As a consequence of the enlargement of the liver, anasarca may be a symptom. Syphilis is much rarer in America than in other countries and syphilitic enlargement of the liver is consequently rather rare. A number of cases of the disease have, however, been reported in America and have been carefully studied.

Classification.—Syphilitic disease of the liver may be classified under three groups, namely, gumma, syphilitic cirrhosis, and either of these with icterus and the changes induced by the icteric condition. The history of a characteristic case was given. The patient was a man, thirty-four years of age, who had his chancre six years before. He remained well and strong notwithstanding the syphilis, but began to complain of some digestive symptoms several years ago. The first noteworthy symptom was belching of gas; then he had severe pains after eating and became nervous and restless and sleepless at night. He lost 24 pounds. Physical examination showed the presence of distinct resistance in the gastric region. A tumor-like area about the diameter of a silver dollar could be felt in the pyloric region. The gastric chyme was examined because there was a suspicion of the presence of cancer. Nothing to confirm this suspicion was found. Hydrochloric acid was slightly lessened in amount, but there was no lactic acid present.

Treatment.—As there was syphilis in the history, the patient was given mercury rather freely and soon began to improve. After about

three months practically all of his symptoms had disappeared. The patient was warned that a relapse of his condition might easily occur and was told not to neglect the preliminary symptoms of the recrudescence of the liver affection. Notwithstanding this warning, the liver was allowed to become seriously affected. After about two years he came back because of almost unbearable tension in the abdomen. On the right side an immense tumor of the liver could be outlined, on which a number of coarse nodules, the size of a walnut, could be felt. One of the large knobs was the size of an apple. The lower level of the liver dulness extended from the umbilicus around into the flank. The upper border of the liver dulness was about normal. The spleen was not much enlarged. Inunctions of mercury were tried and iodide of potassium was freely used. Under this treatment the diminution in the size of the liver was constant and marked. This diminution could be followed from week to week. In between six and seven weeks the liver had returned to its normal size.

Symptomatology.—Usually the initial symptoms are pains in the right hypochondrium and at times in the epigastrium. These pains are sometimes so severe and localized that because of their position they are taken for gallstone colic. The painful symptoms have usually been preceded by digestive symptoms for some time. Loss of appetite is often a marked early feature of the disease. Constipation occurs quite commonly and diarrhea is a rarer symptom of the disease. Loss of weight nearly always occurs, but it is not so marked as during the growth of neoplasms. The other signs characteristic of cancer, cachexia, weakness, bad color, with anemia, are not so prominent in syphilis. Icterus occurs quite commonly. It may be one of the first symptoms of the disease and then may disappear completely, or may persist until the syphilitic condition is entirely cured, or the patient succumbs. When it occurs at the beginning of the affection and disappears later, the jaundice is due to a catarrhal icterus. When the jaundice is persistent, it is due to mechanical interference. In all cases enlargement of the liver occurs. When there are gummata, these occur as nodules. In syphilitic cirrhosis of the liver there is hypertrophy of the whole organ with overgrowth of connective tissue between the lobules of the liver and the organ becomes more or less regularly enlarged and quite hard. Enlargements of the left lobe of the liver are said to be more suspicious of syphilis than enlargements in the rest of the organ, but this symptom is not of much differential value.

Differential Diagnosis.—Where a tumor of the liver can be demonstrated, even if there is no history of syphilis, antisyphilitic treatment should be tried. The therapeutic test is one of the best pathognomonic differentials that we have. Where simple enlarged liver exists, it is extremely difficult to differentiate it from syphilitic hepatitis. Syphilitic enlargement of the liver also resembles very closely hypertrophic cirrhosis. This latter disease is apt to improve, at least at first, under the administration of iodide of potash, so that the iodide test alone does not determine the presence of syphilis. The hardness of the liver does not enable one to distinguish cancer from syphilis, though usually malignant disease is harder to the touch than are the syphilitic tumors. Some syphilitic liver conditions give, however, very unyielding induration. Examination of the blood may prove of some assistance. There is an increase of eosinophiles in the blood during syphilitic invasions of viscera, according to Neisser.

Alcoholic Cirrhosis.—With regard to alcoholic cirrhosis, drunkard's liver, the history must be the main diagnostic aid. In alcoholic cirrhosis the spleen usually enlarges later than it does in syphilitic cirrhosis. With regard to syphilitic hepatitis it must be remembered that sometimes iodide of potash does no good, because the connective tissue in the liver has become fully formed and no longer yields to the absorbent effect of the iodide.

Prognosis of Syphilitic Liver.—The prognosis of the disease is good if the diagnosis is made reasonably early. The presence of ascites soon makes the prognosis unfavorable. The larger the amount of fluid in the abdomen and the longer it is allowed to remain there, the more harm is done. The increase in intra-abdominal pressure very soon interferes with the functions of the organs and produces lasting pathological changes in them. Dr. Einhorn has had one death out of his ten cases and even this improved under treatment. All the others are living and in reasonably good health.

Treatment.—The drug treatment consists of the use of a mixture of potassium iodide and sodium iodide, two to four drams a day at the beginning and gradually increased to five to six drams a day. A combination of these two salts is better than either one of them and it gives much better satisfaction than does the potassium iodide alone. The antiluetic treatment should be continued for from three to four months. Where anemia exists arsenic should be used and also iron. A combination of arsenic and ferric iodide is a very efficient remedy. For ascites, puncture should be made as soon as the pressure gives serious inconvenience. Delay in evacuating the serious fluid in the abdomen is always productive of at least functional visceral mischief. Milk and eggs should be the main part of the diet and bland foods should be chosen with a great deal of care.

Mucous Colitis.—Dr. Henry Koplik read a paper on the intestinal intoxication occurring in mucous colitis in young children. He said that in many cases the prominent symptom of

mucous colitis is an auto-intoxication. There is evidently incomplete digestion followed by the absorption of poisonous peptones. As a rule these poisonous peptones are neutralized in the intestinal walls or in the liver. When this neutralization fails to take place, the work of elimination is thrown upon the kidneys and the indication of this is the presence of acetonuria and diaceturia. As the result of the irritation of these substances, the kidneys fail to act properly and certain uremic symptoms come to complicate the disease.

Symptomatology.—One of the prominent symptoms of the disease is vertigo. Occasionally there is a certain amount of delirium. Stupor is not uncommon and headache is frequently complained of. The resistive vitality of the heart and lungs is lowered, these organs are apt to suffer in their function and the general nutrition is disturbed. A special form of the mucous colitis occurs in children at the age of from three to six years. As a rule, they have been constipated from infancy, or at least have had long constipated intervals. During these intervals some food is apt to disagree with them, particularly, for instance, unboiled milk or vegetables and then they begin to show signs of nutritional disturbance. They become anemic, slow to understand things, peevish and irritable. When the interval passes, they become bright and good and healthy once more. It is evident that the changes of disposition are associated with intestinal toxemia. Such cases may easily develop sudden symptoms, more or less alarming in character.

Mucous Evacuations.—Such children usually have a certain amount of mucous colitis the main symptom of which is the presence of mucus in their stools. Eustace Smith said that we do not as yet understand why these mucous stools occur, nor the true source of the mucus. Our knowledge has not become more definite since he wrote. A typical case makes the condition more easy to understand. The patient was a child of six years of age, bottle fed, and had suffered from a slight amount of rickets. During infancy there had been a severe attack of acute gastro-enteritis and this had been followed by subacute gastro-enteric inflammatory conditions. During an attack of grip, pericarditis had set in and recovery from it had been slow. In spite of the free use of cascara, scybala were always passed in stools and constipation continued to exist.

The Attack.—Before one of the exacerbations of the disease the child became pale and listless and rings were noted under the eyes. There was some vertigo and disinclination to move around much. Nausea existed for some time and when water was asked for, vomiting occurred. The vomit consisted first of food and then of glairy mucus. The vomiting occurred even when lying down and even albumin water was not retained. The pulse was full and bounding, rather high pressure, and 120 to 140. Some albumin was found in the urine and small hyaline casts. The condition stimulated uremia somewhat, but the kidney disturbance did not seem to be the real basis of the pathological condition. There is often some pain complained of in the abdomen, but there is no tenderness on pressure. In one case in Dr. Koplik's recent experience the presence of the pain aroused a suspicion of appendicitis. The differential diagnosis was not, however, very difficult owing to the absence of any localized tenderness.

Toxemic Symptoms.—The patients are pale and anxious looking, with something of the collapsed look of those who have taken poison. Professor Senator has noticed, on several occasions, the odor of hydrogen disulphide on the breath. In one case in Dr. Koplik's practice, the odor of the breath was the same as that of the flatus. In this case the father was a physician and the phenomenon was noticed a number of times. This odor is not, however, invariable and a peculiar mawkish odor may be noticed. Once in Dr. Koplik's recent experience the breath had a sweetish smell. At times, at the end of one of the attacks, the stools may contain mucous casts of the bowel. There is always an abundance of mucus in the stools toward the end of an attack.

Apparent Recovery.—At times there is apparently complete recovery from the condition. The patient becomes bright, regains strength and weight and only the constipation remains as a reminder that the severer condition will probably return. The acute exacerbations really seem to be crises represented by a culmination of the effects of the accumulated mucus and other intestinal material. There is never any anasarca, so that despite the urinary symptoms and the bounding pulse, there is no true uremia. There is an increased elimination of ammoniacal products through the urine.

Treatment.—The best remedy is absolute rest. The giving of all food by the mouth is stopped and exclusive rectal feeding must be resorted to. Somatose injections at a temperature of 110° F. every two hours are valuable. Strychnine must be used freely, the recumbent position must be maintained until the patient is strong again. The use of cream and fat is apt to do harm. Alarming symptoms may follow nausea that absolutely forbids the taking of food for a long time; the diet must then be limited to skim milk and to vegetables that leave little residue. As a rule, bake potatoes and purée of peas are well borne. If spinach is eaten it is often found in the stools.

Prophylaxis.—The sign that an attack of the severe condition is supervening is increased pallor with restlessness and coated tongue, capricious appetite and increase of the constipation. The free use of Carlsbad salts may forestall an attack and, by relieving the bowel of its accumulation of material and draining the blood of some of its serum, and so lessening its index of toxicity, may prevent severer symptoms.

Types of Intestinal Toxemia.—In the discussion Dr. Jacobi said that the amount of urea

excreted and the absence of edema shows that there is no true kidney disease underlying the symptoms. Albumin is found in the urine whenever there is intestinal intoxication. There are two forms of gastro-intestinal toxemia. The first is due to the absorption of noxious material in the upper part of the digestive tract, the stomach and small intestines. The other is due to the absorption of toxins in the colon. Mucous colitis and its attendant train of symptoms are evidently due to the putrefaction of fat and albumin in the colon. The change in the albuminous products gives rise to the ammoniacal material in the urine. As a rule, too much fat is crowded into children. Nurslings have ten per cent. of fat in their feces. Human fat and cow's fat are very different, so that the infant is able to dispose of less of the cow's fat. The presence of unused fatty materials gives rise to fatty acids. These inevitably cause toxic symptoms. It is the custom to fatten babies with the idea that they must be healthy when fat, although this is by no means considered the rule in older people.

Milk Reduction.—For fifty years Dr. Jacobi has pleaded for milk dilution and for the reduction of fat and albumin contained in cow's milk. Albuminoid material, when not digested, putrifies. More cereals should be given than is at present the custom. There is no better disinfectant for the intestinal tract than a small amount of starch. Professor Huebner of Berlin has been converted to this position within the last few years.

Danger of Nephritis.—Dr. Chapin said that this train of symptoms, obstinate constipation and then an interval of offensive stools, with depression of the patient, is a familiar clinical picture to those who see much of children's diseases. The question of a kidney complication is well raised. There is no doubt that there is some kidney irritation. If the temporary condition is allowed to persist, it will give rise to nephritis. Constant passage of irritant material gives rise to parenchymatous nephritis. This is really the origin of the insidious kidney disease that develops so often in latter life, apparently without any reason. At times in the midst of these attacks the lungs suffer as well as the kidneys. Pneumonia is not an infrequent complication.

Chronic Intestinal Toxemia.—Dr. Southworth said that acute intestinal toxemia is well known, but chronic intestinal toxemia is not recognized sufficiently. It occurs always with constipation and may in sensitive nervous patients give rise to epileptiform attacks, so that the physician may suspect epilepsy. However, these symptoms disappear completely. Malodorous stools have a very persistent smell that even clings to the clothing. The treatment consists mainly in the regulation of diet, but the use of salol will be found not only to give good intestinal disinfection, but it also serves to reduce the irregular temperature which is so frequent an accompaniment of this form of intestinal intoxication.

Fulminant Symptoms.—At times in Dr. Southworth's experience, especially in delicate children who have not been well cared for, the symptoms of intestinal toxemia may become fulminant in character. The pulse becomes thready in character collapse ensues and death takes place from overwhelming toxemia. The bronchopneumonia of these cases usually occurs in the lower lobes of the lungs posteriorly and may give rise to the idea of a hypostatic pneumonia.

Liver Tumors.—In discussing Dr. Einhorn's paper Dr. Weir described certain cases that he has recently had under observation. In one there was a tumor in the hepatic region and the patient complained of gastralgia. It seemed as though the gall-bladder were affected. An exploratory incision was made and some of the scars on the liver surface were found to have the radiate, glistening character of syphilitic cicatrices. The wound was at once sewed up and recovery followed under antisyphilitic treatment. In a second case a slight swelling was found in the hepatic region and gave a good deal of discomfort. An incision evacuated an amount of bloody fluid and then considerable pus. A quantity of calcified material was found in a hole in the liver and this also was removed. The patient improved on mixed treatment, though there seemed very little hope for him.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held June 6, 1901.

The Vice-President, Herman Knapp, M.D., in the Chair.

Presentation of Dr. Thomson's Portrait.—Dr. W. M. Polk presented to the Academy a portrait of Dr. William H. Thomson, its former President. Dr. Polk said that Dr. Thomson's picture is a worthy addition to those already there. The fact that Dr. Thomson has been president of the New York Academy of Medicine (1899-1900) is in itself a mark of unusual standing in his profession. Nevertheless, Dr. Thomson's most distinctive qualities have perhaps been shown in his work as a teacher. A physician of wide experience and influence he has the rare gift of making the bare outlines of a dry subject take hold of his audience. He recognized early that the successful teaching of therapeutics involved not only talks on the dosage portion, but also the consideration of the physiological action of the remedies. He followed his idea so successfully and fascinatingly that his example is followed now wherever materia medica is taught. The subject, from being one of the dryest, has thus become one of the most interesting. Dr. Polk said that it is always easier to dwell upon the virtues and excellent qualities of a man who is no longer among the living than to speak of a contemporary, no matter how deserved the words of praise are in truth. However, the members of the Academy of Medi-

cine hope that it will be many years before one will be free to speak thus of Dr. Thomson, and when that time does come it will doubtless be said that he was the peer of any of those whose portraits are already on the walls of the New York Academy of Medicine.

Freezing-Point of Urine.—Dr. J. H. Huddleston read a paper on cryoscopy, the method of determining the constitution of urine by finding its freezing-point. As early as 1870 Bouchard employed this method in the examination of the urine. Malasser and Hamburger followed in 1872. In 1891 Dreser took it up and finally Koranyi began his studies in 1894. Koranyi's investigations were given to the world in 1898, but at the International Medical Congress in 1900 the method received its first extensive public notice. Outside of Germany and France, however, the method has as yet received comparatively little attention.

Law of Cryoscopy.—Cryoscopy is based on Raoult's well-known law and on Koranyi's theory of molecular interchange in the convoluted tubules of the kidney. Raoult's law may be stated briefly as follows: The lowering of the freezing-point of a solution is proportional to the number of molecules dissolved in the unit of volume of the liquid whatever be the nature and weight of the molecules. Of two urines, then, the one whose freezing-point is lower will contain more molecules in solution than the other. The value of urine as an excrementitious product depends on the number of molecules of dissolved material that it carries out of the organism. The number of molecules dissolved in the urine represents also, within certain limits, the permeability of the kidney. This principle is not absolutely true, because the sodium chloride dissolved in the urine cannot be considered an excrementitious product, as it passes out unchanged. Allowance has to be made therefore for the chloride molecules present by estimating the amount of chloride in the urine.

Koranyi's Theory.—Koranvi holds that water, containing sodium chloride in such amount that the solution has the same osmotic tension and therefore the same freezing-point as the blood plasma, is filtered through the walls of the glomeruli of the kidney. This solution, as it flows through the tubules and Henle's loops, returns to the blood a certain amount of water and a certain number of molecules of the sodium chloride and receives exactly the same number of molecules of more complex substances; in fact, it takes on the character of urine there. If the glomerular filtration is rapid the flow of urine is rapid and the rate of molecular interchange in the tubules per unit of urine is slow. Such would be the case with high arterial tension. On the other hand, if the glomerular filtration is slow the flow of urine is slow and permits a high rate of molecular interchange in the tubules. Such would follow in renal stasis or in injury to the glomerular wall as in glomerulo-nephritis. Again, no matter what the rate of urinary flow, if the epithelium of the tubules performs its work imperfectly or obstructs the interchange, the rate of that molecular interchange must be lowered. Such would naturally follow in tubular nephritis, or in any other organic or functional affection of the tubules.

Value of Cryoscopy.—The proofs of the value of cryoscopy must be found in clinical experience with the method and the determination of the accordance of its results with those of chemical observations made in other ways, as with the methylene blue test and with autopsies. A certain number of autopsies are on record in which the conditions present in the heart and kidneys were predicted by the results of cryoscopy, but as a clinical method it is not yet well worked out. Dr. Huddleston's own experience is limited, but, as far as it goes, testifies to the agreement of inferences from cryoscopy with those drawn from usual clinical methods. Comparisons are difficult, however, for urinary cryoscopy is pre-eminently a test of function, independent of structure.

Determination of the Freezing-Point.—Dr. Huddleston uses the method advised by Prof. E. H. Loomis of Princeton, who has been interested for a long time in the observation of freezing-points of solutions, for determining the freezing-point of urine. Professor Loomis' method is to place the test-tube in another tube a trifle larger, keeping them apart with a rubber band. The inside tube should be bottle-shaped at the bottom, so that the stirrer may go to its lowest point and dislodge any ice that would otherwise tend to mass itself there. The thermometer may be held in place by thrusting it through a cork. The stirrer may be a simple piece of spiral wire. There is then prepared a mixture of finely-pounded ice and water. This is put in a vessel of glass heavily wrapped with felt. Sufficient salt is added to this mixture so that the temperature is about that of the freezing-point of urine. The test-tube is filled about a third full of urine and exposed to the freezing mixture until the temperature of the urine has fallen about three- to four-tenths of a degree below the temperature at which the urine freezes. A tiny crystal of ice is dropped into the overcooled urine. This at once begins to freeze and the temperature rises, finally stopping at the freezing-point. This requires about one minute and a reading of the thermometer is then taken. This method determines the freezing-point within $^1/_{1000}$ of a degree Centigrade. Professor Loomis says that the instruments made by R. Fuess of Berlin, Germany, are the only ones that have given him satisfaction. Dr. Huddleston himself has found it helpful to use for the double tube two vials with flat bottoms and to put in the outer

sufficient absolute alcohol to make its level the same as that of the urine in the inner tube.

Foreign Methods of Freezing.—Foreign workers have advised cooling the urine by ether or carbon bisulphide rapidly volatilized by a current of air. The mercury falls slowly to a certain point and then suddenly, with or without the addition of the particle of ice, rises to the freezing-point; while it is rising it is especially necessary to keep the urine well stirred. After a moment, when more or less of the urine is frozen, the temperature gradually falls again to correspond with that of the freezing mixture. It is necessary, therefore, to take the highest point to which the mercury ascends as the freezing-point. The time necessary for this observation varies from fifteen to twenty minutes.

Precautions.—Certain precautions are necessary: The urine must not have undergone any fermentation, as the number of molecules and the freezing-point are affected by that change, freezing throws down a precipitate; the urine must be diluted until that action is avoided; no antiseptics and no medicine must be in the specimen. The percentage of sodium chloride is determined by Volhard's method. It must be remembered that, while cryoscopy is a notable advance in the application of quantitative physico-chemical methods to clinical work and while it may furnish information of considerable value in diagnosis and prognosis in cases of cardiac disease and to a less extent in other cases, it is distinctly a laboratory method requiring time and care.

Dr. Huddleston in conclusion expressed his obligation to Prof. E. H. Loomis of Princeton for much kind advice as to method and to Dr. J. J. Walsh of New York for the stimulation he gave toward the study of the subject of the paper.

Cryoscopy and Surgery.—Dr. B. Lapowski said in discussion that the method promises great things in kidney surgery. When one kidney has to be removed the important question is the condition of the other one. During the last ten years the custom has been to take urine separately from each kidney. The urine thus obtained was then examined microscopically and chemically. Nevertheless, there are cases on record in which the examination was made with all the care possible and the results seemed to justify the operation, but the patient died within twenty-four hours of uremia, not having passed one drop of urine. Cryoscopy can, perhaps, tell why these things have happened. The kidney has two purposes, the eliminative and the functional. Some ingredients are produced by the kidney alone, such as hipuric acid, for instance. Cryoscopy is a functional as well as an eliminative test.

Dr. Lapowski, however, does not think it sufficient to pay attention only to the urine. The blood also must be considered. To arrive at a correct conclusion one must try to determine not only what comes out of the kidney, but also what is brought into it. There are times when it is of the greatest importance to the surgeon to know, if possible, which organ is primarily affected, the heart or the kidney. Therefore the density and freezing-point of the blood should also be ascertained.

Dr. Lapowski congratulated Dr. Huddleston on his paper, the first one presented in this country on this subject. Cryoscopy is not only an advance in diagnosis; it is a method which will enable the physician to follow his cases more intelligently.

A Pessimistic Note.—Dr. Alfred Mayer said in discussing Dr. Huddleston's paper that he for one must strike a pessimistic note. Every practitioner has seen renal cases in which one kidney was absolutely cut off from activity by its sympathy with the other. Dr. Mayer has seen renal calculus limited to one kidney, where there was complete anuria, lasting from one to three or four days, during an attack of renal colic. The other kidney was perfectly healthy. It had refused to act merely out of sympathy. The pessimistic note is, Will or will not the surgeon get complications like this?

Dr. Huddleston said in closing the discussion that he agrees with Dr. Mayer as to the gravity of the question of complications arising in kidney surgery, which cannot be anticipated by any test. A kidney has been known to be diseased, and yet the patient had done well after operation, while again the kidney remaining might show no pathological changes and yet not work. Cryoscopy is still open to criticism, but it does show some advance in methods of diagnosis. As for the examination of the blood advocated by Dr. Lapowski, it adds a distinct element of danger in run-down cases. Koranyi seems to think it useless unless 10 to 15 centimeters of blood are employed, which is too much to take from the patient.

The Most Insidious Diseases.—Dr. Louis Faugères Bishop said the disease which the family physician fears most are not those which have definite names and figure most prominently in health reports. They are rather those which touch on the domain of the heart and the kidneys —Bright's disease, senility, arterial degeneration, and so on.

Extreme Arterial Degeneration.—Dr. Bishop showed a heart which was a remarkable example of extreme degeneration. It was not the heart he had meant to show as illustrative of some of the things he had to say, but one that had been sent instead by mistake. Nevertheless, it was so remarkable that he felt it was of sufficient interest to show under the circumstances. The patient was brought into the hospital in a state of collapse and aphasic. Dr. Bishop suspected extreme thrombosis of many vessels. The temporal and radial arteries stood out, extremely atheromatous. As the man showed some pulmonary symptoms he was put in the consumption ward. Before death occurred the man became very delirious. Dr. Bishop suspected white

thrombosis in the heart, as an explanation of the bad condition and the delirium. At the autopsy he found a white thrombus of considerable size in the right and left side. The left ventricle was hypertrophied and the coronary arteries supplying the right ventricular wall were diseased and thickened and had a distinctly nodular feel under the finger. The right side also showed fatty degeneration of the muscular elements. Dr. Bishop presented also the heart of an old man, who had an extreme kyphosis with a large spinal curvature under the left shoulder. He was thus deformed for eighty years and the heart was dented by the pressure of the spinal column on it.

Symptoms of Arterial Degeneration.—Arterial degeneration is usually marked by ruptures of the stiffening blood-vessels. Sometimes these cause hemorrhages into the lungs which are not very serious, but a rupture into the brain is a grave condition. There is greater danger, however, from secondary disease caused by arterial degeneration. These are the diseases of the heart and kidneys that arise from the thrombosis of chronic intoxication and overwork and the aneurism of the physical toiler. The degeneration is most interesting in the smaller vessels. Early recognition alone will enable us to combat the conditions that lead to cardiac and nephritic changes. The thickening of the arterial walls narrows the lumen and emphasizes other vasoconstrictions. This is most evident in the effect upon the brain. There is dizziness, occasional clumsiness of motion, sometimes a slowness or lack of response in a limb and mild aphasic symptoms. Once these conditions have become advanced and the connective tissues are fully formed, improvement is impossible.

The Victims Are the Useful Individuals.—The saddest aspect of arterial degeneration is that it attacks the members of the community who are the most useful and the most successful. The slothful and the indifferent are in no danger. It is typical in young, successful business and professional men, into whose lives hard work and a certain amount of dissipation enters. Heredity also plays a part in the tendency to arterial degeneration. The life of the blood-vessel in the main depends on the use made of it. The condition of degeneration is slowly developed and, in the meantime, the subject is often the type of health and vigor, the high blood-pressure to the brain stimulating energetic and complex activity. The color of the subject is usually ruddy, the walk is firm, the muscles well nourished, the digestion good. It is often the characteristic condition of the active man of many affairs, as well as of the woman in the whirl of social functions. Sometimes, however, the subject is slightly built and in contrast to the ruddy type, is pallid and nervous. These are generally the types characterized by indigestion.

Hygienic Measures.—The first thing is to remove as far as possible the cause of the condition. Syphilis figures more frequently in the etiology of arterial degeneration than seems to be generally thought. It is a disease of the intoxications—intoxication of alcohol, the intoxication of overwork, and the intoxication of indigestion and syphilis. Alcohol is a difficult factor to combat. Few who are addicted to its use will give it up. The physician must therefore insist at least upon its limitation to table use. In arterial degeneration digitalis and iron are contraindicated. Digitalis will hasten degeneration and excess of iron acts as an astringent and further interferes with the circulation. The alkalies, water, and the bitter tonics are the only agents that have a direct bearing on the condition. Moreover the necessity of rest, at all times and everywhere, should be impressed on the patient.

Symptoms Resembling Neurasthenia.—Many of the symptoms of arterial degeneration resemble neurasthenia. There is sometimes a momentary loss of power to grasp things, a sense of pressure at the back of the head. In these cases the bromides are useful. Sometimes there is a sort of chorea of the blood-vessels causing a hot sensation on the back and in the head, somewhat similar to the symptoms characteristic of the menopause in women. For these cases iodide of soda should be given in small and persistent doses. The latter type may also be given $^1/_{100}$ of a grain of nitroglycerin three times a day for one week each month. Business matters and personal affairs must be adjusted so as to avoid exhausting responsibilities and depressing worries. Work must, in fact, be given up to a certain extent. In the pallid, nervous, low-spirited, moody cases, associated with indigestion, this is especially necessary. Sometimes there is a rupture of the small blood-vessels of the conjunctiva. While it is in itself insignificant it may precede more serious symptoms, and in at least one recorded case sudden death followed.

Analogy between Nervous and Arterial Systems.—There is a close analogy between the degeneration of the nervous system and that of the arterial system. This much may be said for neurasthenia—a good neurasthenia frequently saves a man from an arterial degeneration later in life. It puts a damper upon his vital forces and inclines him to that letting-go of things which is his saving. This is especially true of those who have been of sanguine, enterprising and active habits. In both the diseases, prominent factors that have to be combated are the chronic intoxications of overwork, diet, drink and syphilis.

American Association for the Advancement of Sciences.—This large and influential body of scientists held their annual meeting Tuesday, Wednesday, Thursday and Friday of this week at Denver The attendance was large and many papers of unusual scientific interest were read. A special excursion to the Grand Cañon of the Colorado was planned to take place at the close of the meeting.

ORIGINAL ARTICLES.

A STUDY OF THE TEMPERATURE LAWS IN EPILEPSY BASED ON ONE THOUSAND OBSERVATIONS.

BY WILLIAM P. SPRATLING, M.D.,

OF SONYEA, N. Y.;

MEDICAL SUPERINTENDENT, CRAIG COLONY.

BOURNEVILLE, editor of the *Archives of Neurology*, physician to the Bicêtre Hospital, Paris, disciple of Charcot, and editor of the complete works of the latter, seems to have been both the earliest and the most voluminous writer on the above subject. His studies date from the year 1869 to the present decade. His graduation thesis was upon the temperature in cerebral diseases, and he has contributed to medical literature at least a dozen papers upon the temperature in epilepsy and allied conditions alone. His works may be divided chronologically into two periods, the first from 1869 to 1886, the second from 1886 to the present time.

The reason for this subdivision is as follows: During the earlier period Bourneville had, to his own satisfaction and apparently to that of his colleague and that of most physicians, so thoroughly demonstrated the phenomena of the rise of temperature connected with epileptic paroxysms that the fact was taught dogmatically by Charcot and other eminent men. However, in the year 1886 a German, Witkowski by name, attempted to discredit both the observations and conclusions of Bourneville. The latter then repeated his experiments very carefully and published new and exhaustive data; and his colleague and disciple, Prof. Lemoine of Lille, also conducted a series of observations even more exhaustive than Bourneville's, so that between the two the facts seem established for all time.

It is somewhat unfortunate, perhaps, that of the writings of Bourneville during the first period, that is from 1869 to 1886, not one is to be found in the library of the New York Academy of Medicine, nor are there any reviews or extracts in temperature literature, except a few quotations elsewhere presented in this paper.

It is fortunate, however, that all of Bourneville's writings of the second period, namely, from 1886 to the present time, are to be found in this country, and, as the author himself repeatedly says, he confirms all his earlier findings, thus justifying, he claims, his original views which had been attacked by Witkowski. It is unfortunate that none of the studies of Witkowski are accessible at this time.

It is of interest and may be of some value to give a few citations from Bourneville's earlier writings.

Seguin[1] sums up certain observations which include Bourneville's: (1) During and between isolated seizures the temperature fluctuates. Clouston first noted an initial fall preceding the attack, but Charcot, Bourneville and others note a rise during the paroxysm and a fall between the paroxysms. (2) During the status epilepticus the temperature progressively increases, the remissions being less and less marked and in a few hours it attains 40° to 41° C. (3) The epileptiform attacks of general paralysis of the insane are always followed by high temperature which persists several days. (4) The epileptiform convulsions of hysteria show a relatively low temperature during a high degree of status epilepticus. In one case of convulsions persisting three months, the maximum temperature was only 38.5° C., while the mean was 37.4° to 37.8° C.

Gowers[2] cites Bourneville's statement that in status epilepticus with fatal termination the temperature runs up to 105 and 107° F.

Rosenthal[3] cites Bourneville on status epilepticus, the high temperature (40° to 43° C.), its persistence during the intervals between convulsions, and even increasing after convulsions have ceased.

Bourneville also mentions that his views were approved in the works of Laveran and Teissier (1876, page 63) and Axenfeld and Huchard (1883, page 782). The few authors, then, who quote from Bourneville's earlier writings, speak only of the high temperature of the status epilepticus.

Witkowski, who attacked Bourneville's views in the article "Ueber epileptisches Fieber, etc.,"[4] says that he has taken the temperature of epileptics for many years and, while there is often enough a slight rise of temperature during the paroxysm, it is often absent, and that there is no necessary relationship between the two. The exact cause of the phenomenon is undetermined. Witkowski, however, gives no figures or tables and, when his statements are contrasted with the careful, scientific and thorough work of Bourneville and Lemoine, his paper would seem to make a poor impression; in this case it appears that it is the Frenchman who is patient and accurate, and the German who is loose and flighty.

Before proceeding with a closer description of the work done by Bourneville, let me review one of the observations made by Seguin, as cited by Bourneville in his earlier writings.

In referring to the temperature in the epileptiform attacks of general paralysis, Seguin says:

[1] Medical Thermometry, 1876, page 226.
[2] Epilepsy, etc.
[3] American Edition, 1879.
[4] Berlin klin. Wochenschrift, Oct. 25, 1886.

"The epileptiform attacks of general paralysis of the insane are always followed by high temperature which persists several days." I am quite convinced that in this statement Seguin is wrong. During 1888-89 and 1890, at the New Jersey State Hospital for the Insane at Morris Plains, I had under my immediate observation twenty cases of general paralysis of the insane, two of whom were women, the rest men. All of them were carefully watched and studied, and not one of them ever had a general epileptiform convulsion or an epileptiform seizure of any kind that was followed by the usual train of post-epileptic symptoms, such as coma, sleep, etc. Most of the cases did have, however, toward the latter part of the second stage of the disease, and before the bed-ridden period of its third stage, frequent monoplegic attacks, convulsive in nature, that generally occurred in the right arm with occasional involvement of the left arm and legs, the rule being that a single member only was affected at one time. In such cases there was never any elevation of temperature, and I am inclined to think that the persistent high temperature following epileptiform seizures in cases of general paralysis, as noted by Seguin, was due not to the seizures but to the inflammatory changes going on in the cortical substance of the brain and which constituted the essential lesion of the disease. Then, again, it is perfectly reasonable to assume that any influence sufficient to disturb the pathological changes in progress would cause a temporary increased elevation of temperature; but it would not arise were it not for the already diseased brain.

Personally, I have never seen any elevation of temperature following epileptiform seizures in general paralysis of the insane that I felt justified in differentiating from the fever that was naturally due to pre-existing conditions and that was symptomatic of the existing brain lesion.

During the latter part of the third stage of general paralysis, when the patient becomes bedridden through sudden rapid progress of the disease, I have observed that the temperature generally runs high, sometimes to 104° F. and above, and that all convulsive phenomena cease when this condition sets in. It would seem that this might be readily explained as being due to the broken-down and exhausted condition of the cells in the brain that produce motion. An actual state of general paralysis has been established. So here we have a high temperature without the possibility of convulsive phenomena in any form.

Researches on the Temperature During Epileptic Paroxysms.—Bourneville and Lemoine's work was based upon over 500 examinations. Of these Bourneville reported sixty-four cases in 1886, but it is not just apparent when these investigations were made. In his *Recherches sur l'epilepsie,* etc., for 1886-1887, he reports 109 cases. In the same *Recherches* for 1891 he reports 66 observations, none of which were made prior to 1888. Lemoine in 1888 reports 182 cases. The grand total is 520 cases.

As a general rule the majority of these observations follow a law and may be described as typical while a small minority are atypical. Of the first series of 64, 60 were typical; of the second series of 109, 82 were typical; of the 66 cases, 58 were typical. Lemoine, who considered the subject from a broader standpoint, found in his 182 cases only a solitary exception to his normal, or type. Lemoine assumed that certain cases were naturally anomalous in the matter of temperature, having abnormally low temperature in health; hence the anomaly in these cases is not referable to the epilepsy but to the patient himself. From Bourneville's standpoint, there would be about 92 per cent. typical and from Lemoine's point of view upwards of 99 per cent.

Method of Conducting Researches.—Bourneville divides all cases of epileptic paroxysms in a fourfold manner: (1) Isolated attacks; (2) serial attacks; (3) cases intermediate between the serial attacks and the status epilepticus; (4) the status epilepticus.

In each of these categories he has sought to determine the temperature laws. Temperature was always taken *per rectum,* and invariably at three periods: (*a*) At the moment of stertor or at the immediate ending of the convulsive attack; (*b*) fifteen minutes after the taking of the first temperature; (*c*) two hours later.

The observations of isolated attacks by both Bourneville and Lemoine are tabulated carefully, the patient's name, etc., being given, as well as the three readings as above. Cases of the status epilepticus and serial attacks are not included, because the temperature was taken under different circumstances and the readings were very different in character. These latter are few in number and must not be confounded with anomalous cases of isolated attacks.

All observations were taken with a Centigrade thermometer. It should be emphasized that the 521 cases appear to be entirely cases of *isolated attacks.* Bourneville's article published in 1886-1887 is entitled *"De la temperature dans les accès isolés d'epilepsie"* and Lemoine's article also bears the same title. It must be remembered that the temperature in serial attacks and status epilepticus was an acknowledged fact and that what the reporters sought to prove at this time was the slight but constant rise of temperature co-existing with an ordinary isolated attack of epilepsy, this being a comparatively frequent phenomenon, while the *status epilepticus* was something newly described. Bourneville, indeed, having been the first to give it a thorough description. In determining the existence of this phenomenon (status epilepticus) one of the most salient points, or characteristics, was the high temperature.

It should be noted that in Bourneville's earlier work on temperature in epilepsy the facts which were uniformly accepted by others referred rather to the high temperature of the newly-described status epilepticus than to the slight but constant rise noted in the ordinary paroxysm; and that the investigations of Bourneville and Lemoine

were undertaken (after 1886) purely to demonstrate this latter fact.

Isolated Attacks.—Bourneville's conclusions were as follows: (1) Isolated attacks of epilepsy augment the central temperature. (2) This augmentation varies from .1° up to 1.5° and even higher at times. The average rise is about .5° or .6°.

Conclusions of Lemoine in Corroboration of Bourneville.—There is an access of temperature during the seizure, which afterward declines progressively. (1) In the majority of cases the elevation is slight, varying from .1° to 1.5°. Allowing 37.5° C. as normal, the elevation may vary from 37.6° to 39° C. Average rise, .7°. (2) It is rare for 39° C. to be exceeded. Out of 182 cases only 2 were beyond this figure. (3) The initial temperature at the moment of stertor is relatively low at times, not rarely being as low as 36.4° or 36.6° C. This is not supposed to denote an initial fall, because in these cases there is a still lower declension both fifteen minutes and two hours later. The cases are explained by an abnormally low normal temperature. (4) When the attack is unusually severe with prolonged stertor, the rise of temperature is more persistent. (5) In the same patient we may find notable differences between the temperature record at different seizures. In fact, it is unusual to find the same reading. (6) That the elevation of temperature is due to the epileptic access is shown by the fall of temperature within fifteen minutes.

Anomalous Cases of Isolated Attacks.—In Bourneville's series of 64 cases, he failed to record any access of temperature in 4 cases. In his series of 109 cases, 14 showed elevation only 15 minutes after the seizure. In 13 others the results were complex—in the majority the temperature was higher after two hours than at any previous moments, while at the 15-minute period the temperature was lower than before or after. In his series of 66 cases there were 8 irregular cases when the temperature was higher at the 15-minute interval than before or after.

Lemoine, in his 182 cases, found but 1 case in which there was an exception to his law of a rise at the access followed by a fall within 15 minutes.

Serial Attacks.—In Bourneville's article published in 1891, he gives his observations on 4 cases of serial attacks, meaning by this term cases in which a number of paroxysms occurred in a single day and on successive days, with intervals of rest. In these cases he took three temperatures as follows: The first at a given time, the second twelve hours and the third eighteen hours later. Of these 4 cases there were respectively five, fifteen, twenty and nine attacks in one day. The first temperature was taken at the moment of stertor after an access. In all the cases, the initial temperature was the highest and the readings at twelve and eighteen hours were progressively lower. The initial temperature varied from 38° to 38.6° C.; the twelve-hour temperature from 37.8° to 38° C., and the eighteen-hour temperature from 37.3° to 37.8° C. It would appear, therefore, that these cases do not differ materially from ordinary isolated cases. (See Lemoine's average.)

Status Epilepticus.—This clinical phenomenon was first clearly described by Bourneville. He characterizes it as follows: (1) Attacks incessantly repeated so that they overlap one another (subintrant attacks); (2) terminate in collapse variable in degrees up to the most absolute and fatal coma; (3) may end in hemiplegia; (4) pulse and respiration always increased; (5) considerable elevation of temperature, which persists during the (brief) intervals between convulsions and increases even when the convulsions have ceased.

Bourneville gives several fatal cases in which the temperature ran up respectively to 40.8°, 42°, 42.4°, and 40.9° C. In 1892 Bourneville reported a similar case in which the temperature was taken up to death. The record shows that the temperature increased slightly each day until at death it was 40.2° C.

Intermediate Cases.—Bourneville reports two cases which he considers stand midway between ordinary serial attacks and the status epilepticus. These are given in his *Recherches sur l'epilepsie,* etc., 1891, but are not especially significant, being thoroughly unique and atypical.

Personal Observations.—My own studies of the temperature laws in epilepsy extended over fifteen months and covered 1,000 records made in 250 cases. These included all types of the disease, though in some of them, such as the so-called hystero-epilepsy, a sufficient number of observations could not be made to warrant any general deductions being drawn. In classifying the types of the disease studied, the old symptomatic designations of grand mal, petit mal, Jacksonian and psychic epilepsy were used as being more generally understood. Something will also be said about the temperature in special epileptic states, as status epilepticus and serial attacks. The data made in each case in recording the temperature included the date, name of patient, hour of seizure, character of seizure, duration of seizure. Then followed three temperature records made immediately after the fit; half an hour after the fit; one hour after the fit, except in 75 cases and in these the second record was made one hour after, and the third two hours after the fit.

The method of taking the temperature in each case was uniform and in accordance with that given by Flint.[5] "The bulb of the instrument is to be placed within the axilla and the arm of the patient folded across the chest, the perspiration having first been wiped away. The instrument should remain in this situation eight or ten minutes. . . The axilla is a much better situation in which to place the bulb of the instrument than under the tongue."

For ordinary temperature observations this latter statement may offer some ground for difference of opinion, but that the axilla is the best

[5] Principles and Practice of Medicine, 5th edition, 1881, pages 98 & 99.

and only possible uniform place in which any number of reliable temperature observations may be made in epileptics immediately after convulsions is a statement that no one familiar with the conditions will for a moment question. After a convulsion many patients are so disturbed, restless, and violent often under automatism, that it would be dangerous to place a thermometer in any other place than under the arm, where the nurse may compress the arm in such a way as to insure a reliable record and at the same time prevent the destruction of the instrument, with possible injury to the patient.

Temperature Laws in Health.—Before proceeding further with a description of the work done in making my own observations, it will be well, as an aid to comparison, to refer briefly to the temperature laws in health and to speak also of the physiological principles governing the production and regulation of heat in the human economy. It is not likely that any one will question the statement that the normal temperature of the body is from 98.4° to 98.5° F.; nor is there room for doubt concerning its diurnal variation, the rule being that it gradually increases during the day, reaching its height between five and eight o'clock in the evening, after which it begins to decline, reaching its lowest point between two and six o'clock in the morning.

Not to have taken into account this diurnal variation appears to have been an omission on the part of Bourneville and others and one that might cause some deflection in the figures obtained, since the general average elevation noted by these observers was so slight as to admit of explanation under the laws of diurnal variation. But I would not be understood as stating that such error was made. I only say that evidence is lacking to show that it was avoided. In my own observations especial pains were taken to do this by recording the exact hour of each seizure; and when we come to study the results in detail the twenty-four hours will be divided into four quarters, so that all seizures occurring during a given quarter may be compared, under equal conditions, with a like number of seizures that occurred during a different quarter.

Modes of Production of Animal Heat.—Foster[6] says: "We may indeed at once affirm that the heat of the body is generated by the oxidation, not of any particular substance, but of the tissues at large; wherever metabolism is going on, heat is being set free. In growth and repair, in the disposition of new material, in the transformation of lifeless pabulum into living tissue, heat is produced. Of all the tissues of the body, the muscles, not only from their bulk, forming as they do so large a portion of the whole frame, but also from the character of their metabolism, must be regarded as the chief sources of heat. Whenever a muscle contracts, heat is given out. When a mercury thermometer is plunged into a mass of muscle, such as the thigh of a dog, a rise of the mercury is observed upon the muscle being thrown into the violent contraction."

Dalton[7] says: "In all instances, so far as observation goes, the production of heat in living organisms is in proportion to the activity of the internal changes going on in the body. Birds and mammals in which respiration is most active have also the highest temperature. Each separate organ has a special temperature of its own, which increases or diminishes according to activity or repose; and since the muscles constitute so large a mass of the body it is easy to understand how continuous muscular exertion should after a time produce a general elevation of temperature. The temperature of the body is increased by muscular activity. It is a matter of common observation, both in man and in animals, that exertion produces an increase in bodily warmth."

Kirk[8] remarks that "As the muscles form so large a part of the body, and as their metabolism is particularly active, it is reasonable to consider the muscular as the chief heat-producing tissue."

Landois and Sterling[9] state: "The muscles form about the half the whole mass of the body, and the bones nearly the other half. In the latter oxidation does not go on actively, so that the muscles must be the great seats of heat-production, or thermogenesis, in the body. This view is supported by the fact that the blood leaving a muscle at rest contains more CO_2 than the blood in the right ventricle. Muscular exercise greatly increases the metabolism and the CO_2 excreted; but at the same time there is great increase in heat production. The muscles, therefore, are the great thermogenic tissues and they yield four-fifths of the heat in health."

As far as it is possible for us at this time to determine, is it not essential that we consider here the influence exerted by the glandular system during the periods of their greatest activity (after the ingestion of food), nor the chemical changes going on throughout all the tissues of the economy, in so far as either of them may influence heat-production irrespective of the control possessed by the nervous system over their actions, for the reason that we do not now know of any established connection between them, acting normally or otherwise, in the production of greater heat elevation as the result of an epileptic seizure; but with the muscular system it is different and so it may be with the nervous system.

In reviewing the action of the nervous system in the production and regulation of heat, Kirk ascribes its power to the influence possessed by the vasomotor system (1) in controlling the metabolism of the tissues, (2) in the power it possesses in regulating the caliber of the blood-vessels, and (3) "there is evidence," he says, "to show that there is another nervous apparatus closely comparable to that which regulates the secretion of the saliva and sweat, by means of which the degree of heat is increased or dimin-

[6] Physiology, 1881, page 580.

[7] Human Physiology, 1875, page 305.
[8] Handbook of Physiology, 1896, page 407.
[9] Human Physiology, 3rd edition, page 364.

ished in the warm-blooded animals, as the occasion requires. This apparatus probably consists of a center which may be reflexly stimulated, as, for example, by impulses from the skin and which "act through special nerves supplied to the various tissues. The position of this hypothetical center is a matter of some difference of opinion. It has been demonstrated that stimulation of different parts of the brain may, among other symptoms, produce increased metabolism of the tissues, with increased output of carbon dioxide and a raised temperature; the parts of which this may be asserted are parts of the corpus striatum and of the optic thalamus. The exact situation of the heat center, however, is at present not known with certainty."

Thermal Cortical Centers.—Eulenberg and Landois discovered an area on the cortex cerebri whose stimulation produced an undoubted effect upon the temperature and condition of the blood-vessels of the opposite extremities. This region generally embraces the area in which, at the same time, the motor centers for the flexors and rotators of the fore limb and for the muscle for the hind limb are placed. Destruction of this region causes increase of the temperature of the opposite extremities.[10]

Cerebral Centers.—Ott, Aronsohn, Sachs, Richet and others have shown that if a needle be thrust through the skull and brain so as to injure certain more deeply-seated parts, there is a rise of temperature and increased heat production for several hours. Ott gives three areas which, when so injured, cause these effects: (1) A part of the brain in the median side of the corpus striatum and near the nodus censorius; (2) a part between the corpus striatum and the optic thalamus; (3) the anterior end of the optic thalamus itself.

Ferrier[11] says: "If the nervous system has a direct influence on the excitation and nutrition of muscles and glands apart from the usually concomitant vascular changes, it would follow by implication that the nervous system must have a direct influence on the production of heat, seeing that the muscles and glands are the chief foci of heat production in the body, and that in certain cases of cerebral and spinal lesion, as well as in functional disorders of the nervous system of an undetermined nature, there may be abnormal heat production of a local character out of all proportion to mere vascular dilatation—and to such extent as, if general, would be incompatible with life, seems to be established by numerous and well-authenticated observations." Ferrier does not believe that there is a special heat center, considering it an anatomical impossibility for such a center to have afferent and efferent relations with every part of the body.

Green[12] says: "Cases of nervous injury or disease not uncommonly occur in which one cannot help suspecting either that thermo-inhibitory centers or fibers are destroyed, or that thermogenic fibers or centers are irritated. Hale White has brought a number of such interesting cases together. In a most interesting case of bullet wound of the head accompanied by fever, not otherwise explained, it was found that the motor area of the cortex corresponding to Eulenberg's and Landois' heat center in the dog had been destroyed. It has long been known that injuries and tumors of the spinal cord, along which thermal fibers must pass, are apt to cause marked fever."

It will be well for us to bear these statements of Foster, Dalton, Kirk, Landois and Sterling, and Ferrier in mind, for they will be of great value when we come to study directly the causes of increased heat dependent upon an epileptic seizure.

The following summary exhibits all the observations made in 828 seizures and does not include 172 others which were tabulated far enough only to add confirmation to the results given in specified form.

Each group was studied in order, as follows: Group I., 516 grand mal seizures; Group II., 133 petit mal seizures; Group III., 81 psychic seizures; Group IV., 50 grand mal seizures with extended observations; Group V., 25 petit mal seizures with extended observations; Group VI., 17 cases of status epilepticus; Group VII., 5 cases of serial attacks.

It is impossible here to give the details of the observations, but the following facts were brought out in these studies.

Summary of Results.

Group. I.—This group comprised 516 grand mal seizures. The average duration of all the seizures, including the stage of active convulsions only, was a fraction over 1¾ minutes, the longest being 5, the shortest ½ minute. A single fit only lasted 5 minutes with a temperature of 99.6° F. immediately after, dropping to normal 30 minutes later. In five cases the fit lasted 4 minutes; all followed by increased temperatures, ranging from 99.2° to 100.6° F. immediately after. In 10 others, in which the fit lasted ½ minute only, the temperature was increased in all from .2° to 3.5°. This fact is mentioned to show the apparent lack of value in comparison between heat elevation following seizures of long duration, as compared with those of short duration.

Taking the 516 grand mal seizures collectively, we find that 297, or 57½ per cent., show an increase in temperature ranging from .2° to 3.5° immediately after the fit. Again, taking the same group of cases, we find that 80, or 15½ per cent., show subnormal temperatures immediately after the fit, ranging from 96.4° F. in one case to from 97° to 98° F. in 31 others. As this subnormal group will not be referred to again, it may be well to state here that after careful study we have been unable to assign any cause for the low temperature in these cases, other than the causes that operate generally to produce low temperatures in other conditions, such as chronic

[10] Landois and Sterling, Human Physiology, 3rd edition page 755.
[11] Functions of the Brain, 1886, page 86.
[12] Pathology and Morbid Anatomy, 1895, page 278.

asthenic diseases of long standing, defective nutrition, idiocy, imbecility, and epileptic dementia complicated with or without para- or hemiplegic infirmities.

Turning again to the 516 grand mal seizures, it will be noted that while 297, or 57½ per cent., showed increased temperature immediately after the fit, 330, or 66 per cent., showed an increase one-half hour later, the highest temperature being 102.2° F., the lowest, 97.4° F. At the third observation, one hour after the fit, 327, or 64 per cent., gave temperature increases above the normal, ranging from .2° to 3.5°.

Group II.—The average duration of the fit in this group was $1^2/_{100}$ of a minute, the longest being 4 minutes, the shortest ¼ minute.

Immediately after the fit 80, or 60 per cent., showed increased temperatures ranging from .2° to 2.5° above normal, while a subnormal record was made in 14, or 10 per cent. of the entire number, the proportion of subnormals being less in this group by 33 per cent. than in the previous grand mal group. The same 133 cases presented at the end of half an hour increased temperatures in 94, or 70 per cent., ranging from .2° to 4.5° above normal, while at the end of one hour after the fit only 70, or 52½ per cent., still showed an increase.

Group III.—The average duration of the fit in this group was a fraction less than in the petit mals, being about one minute. Immediately after the fit 49, or 60 per cent., of them gave increased temperatures ranging from .2° to 1.8° above normal. After half an hour 56, or 69 per cent., still showed an increase; while at the end of one hour 54, or 67⅓ per cent., showed relatively the same heat elevations.

Group IV.—In these cases, 26, or 52 per cent., showed temperature increases that ran uniformly through all the record hours, that is, those showing an increase immediately after the fit showed relatively the same increase at the end of the second hour. It may also be noted that 14 cases of this group that showed low temperatures immediately after the fit showed still lower temperatures two hours later, many of them dropping from slight increases above normal to subnormal.

Group V.—In this group 13, or 52 per cent., showed increased temperatures immediately after the fit. One hour after 16, or 64 per cent., showed increase; while at the end of the second hour after the fit 17, or 68 per cent., showed relatively greater increases than were noted immediately after the fit.

None of the seizures of this group were violent or severe, none lasting more than 60 seconds, so that in looking for the cause of heat elevation in them, we feel justified in at once excluding muscular activity. In many of them the muscles did not play any more important part than that required for the fibrillary contractions of some of the muscles of expression, chiefly those about the mouth, which are so frequently seen in petit mal and psychic seizures.

It is not possible for such muscular activity to increase the temperature of the body to 100° F.; it matters not how important a factor muscular activity may be in creating heat, and in such cases it is entirely within reason for us to assume that there has been a disturbance in the central nervous system, either in the thermal cortical centers described by Landois and Sterling, or, since motion in such cases is so insignificant, in the lower heat centers in the corpus striatum and optic thalamus.

It is a well-established fact in pathology that in disease involving the highest specialized tissues of the body, recovery takes place at a much slower rate than when grosser tissue is involved. By analogy, the same thing is true here. Increased heat of the body, due to simple increase in muscular action, will more quickly pass away than when such increase is due to a deep-seated disturbance of the heat centers of the brain.

Group VI.—The fact that status epilepticus is so often accompanied by extreme heat of the body is so well known and recognized that further arguments on this line would be superfluous here; this group is presented more to make the study of the temperature laws in epilepsy as complete in this paper as possible than for any other purpose. By studying the table, it will be noted that the lowest status temperature was 102.4° F., the highest, 107.5° F. In 11 the temperature ran up to 104° F. and over; and in 9 to 105° F. and over; while 107° F. and over was reached in 2 cases.

Group VII.—The difference between the duration of the attacks in this group, as compared with the duration in the status group, and further compared as to the temperatures that followed in each, is apparent at a glance. The highest temperature following serial attacks was 105.8° F., the seizures that caused it numbering 140, covering a period of 96 hours. In none of the remaining serial attacks did the temperature go above 100.8° F.

Death occurred in 28½ per cent. of the status cases; none occurred during serial attacks.

Conclusions.

1. In his conclusions Bourneville says: "Isolated attacks of epilepsy augment the central temperature." The only logical inference we can draw from this statement is that Bourneville found the temperature increased after every isolated epileptic seizure, and nothing exists in Bourneville's work on the subject to change this opinion.

2. The results of our own observations agree in part only with those of Bourneville, the latter's work having, in our opinion, lost much of its value through failure to properly classify the types of seizures studied and to make due allowance for certain physiological differences in temperature.

3. After making due allowance for diurnal variation, we find that 40 per cent. would be the

lowest of such cases showing increased temperature after seizures, and 70 per cent. the highest, making the general grand average of cases of all types showing increased temperature after seizures 55 per cent., the difference in the results obtained by Bourneville and by us being 45 per cent. The views of such eminent physiologists as Dalton, Kirk, Foster, Landois and Sterling, relative to the part played by muscular activity in creating heat, must in view of the activity of the muscular system in certain cases of major epilepsy have great weight in determining the cause of heat production in these cases, wholly irrespective of any influence that might be exerted by the heat centers in the brain.

4. By the results of our own observations, we are led to believe that in many petit mal and psychic attacks in which muscular activity plays so small a part, and in which the temperature is often increased after seizures, such increase is due to a disturbance either of the heat center that is thought to exist in the cortex of the brain, or of the center or centers that observers believe have been located in the corpus striatum and optic thalamus.

5. We find that subnormal temperatures follow epileptic seizures in greater proportion after grand mal than after petit mal or psychic seizures, the proportion being 15 per cent. of the former to 10 per cent. of the latter types; and that, while we agree in the main with Lemoine as to the cause for such low temperatures, when he says "Certain cases are naturally anomalous in the matter of temperature, having abnormally low temperatures in health," we do not believe that this explanation is altogether sufficient, but that there will usually be found to exist in these cases some chronic disease or general asthenic condition of long standing that lowers the stamina and vitality of the individual.

6. All that has been said by Bourneville, Lemoine and others, relative to the high temperature in status epilepticus, is confirmed by the tabulated results in the 17 cases referred to in this paper.

7. The temperature in serial attacks runs uniformly higher than in isolated attacks, but not so high as in status, serial attacks occupying midway ground, as to frequency, severity, temperature elevations and mortality, between isolated seizures and status epilepticus.

8. As a possible factor in establishing the presence of toxins or other agencies in the body prior to and possibly causing the convulsion, an effort was made to take the temperature in some cases when the aura was of sufficient length, before the attack; but it was done in one case only, and in this the heat, beginning two hours before the fit, ran steadily up to 102° F., when the patient passed into convulsion.

State Medical Society.—The annual meeting of the Pennsylvania State Medical Society will be held in Philadelphia, September 24th, 25th, and 26th.

THE TREATMENT OF PUERPERAL INFECTION.

BY DAVID J. LORING, M.D.,
OF VALPARAISO, INDIANA.

PUERPERAL infection is wound infection, hence, the treatment of puerperal infection becomes essentially the treatment of wound infection. The internal administration of drugs, except when employed to relieve some physiological embarrassment, or to allay pain, is not only of no benefit, but may become positively injurious. This is true for the reason that, with our present knowledge of etiological factors and pathological conditions, it is wholly unreasonable to suppose that we can safely introduce into the general circulation any drug which would either inhibit, prevent or destroy the growth or development of micro-organisms on which we now know every case of puerperal infection depends. Moreover, the dependence on the internal administration of drugs is so delusive and may create such a feeling of security that the proper treatment is postponed until the opportunity of saving life or the prevention of chronic invalidism is past. The proper treatment therefore is surgical and should be prompt, decisive and radical from the beginning. I know of no pathological condition in which the proper surgical treatment, early and thoroughly applied, can save more lives, or prevent so much chronic invalidism as that of puerperal infection, and none the neglect of which has caused so many deaths or resulted in so much suffering for women.

The treatment of puerperal infection should be limited to mean that occurring within the first four weeks after delivery, and treatment instituted for uterine infection later than this should not be considered as having been applied for puerperal infection, notwithstanding the fact that the lesion is the result of puerperal infection. There is so much difference in the condition of the tissues at one week, with the enormously developed lymphatics and vessels, and six weeks after this has past, that the lesion is wholly different and the demand for surgical treatment therefore becomes less imperative. Infections following early abortion, during the first or second month, with but little developed lymphatics and vessels, give rise to less septicemia and partake more of the character of septic endometritis; later abortions, that of infection at full term. The line cannot be sharply drawn between those cases which are purely abortional and those purely puerperal. The dangers seem to bear a direct ratio to the period of gestation.

Before proceeding to the treatment of the infected uterus, the responsibility for the rise of temperature should be placed in this organ. Puerperal women may have a rise of temperature from general causes, and these should always be excluded before determining that the case is one of puerperal infection. Probably seventy-five out of every one hundred women, who have a rise of temperature following labor, will assume a normal condition in a few days if left alone;

[1] Read before the Indiana State Medical Society, South Bend, Ind., May 16, 1901.

but of the remaining twenty-five a few will die and the remainder will recover with permanently-damaged pelvic organs and remain chronic invalids for life, and will always have before them the dreaded thoughts of undergoing some surgical operation. We must not be content alone with attacking mortality statistics, but we must attack morbidity statistics as well. It certainly would be desirable if every physician were able to make bacteriological cultures from the inside of the uterus, and thus determine, with precision, the exact nature of the infecting agent in each individual case; but no two bacteriologists agree on the method of collecting these discharges, and they are still debating it. The fact still remains, after all, that a vast majority of the profession prefer to be governed by clinical symptoms, rather than bacteriological investigation, except when made by the most skilled; and thus, the general practitioner, into whose hands these cases usually fall must either waste valuable time in determining whether or not he has to deal with a virulent streptococcus infection or adopt that plan of treatment which will do good in all cases and harm in none; at least, any sensible physician would, although the theorist might not.

In planning the proper surgical treatment, we should always have in view (1) the limitation of the infected area to the fullest possible extent; (2) the provision of abundant drainage for ptomains and leucomains and other tissue débris, the result of microscopic invasion; and (3) the introduction of some antiseptic, such as iodine in the form of iodoform, which will render the infected field sterile in the shortest possible time.

If these cases are seen early, within the first twelve or twenty-four hours, and we have reason to believe that the infection has gone no farther than the free surface of the decidua, for at one time all infections are superficial, simple intra-uterine irrigation, with normal salt solution or boracic acid, 2 per cent., may and often will effect a cure, and in such cases should be tried with a fair prospect of success. Strong antiseptic solutions should never be used in the uterine cavity, unless the same be followed immediately by curettage. Such antiseptics as bichloride of mercury and carbolic acid are eminently efficient in the destruction of germs, but at the same time they destroy cellular elements and this will always result in sloughing. This sloughing will not only afford abundant material for the further growth of germs, but it also retards regeneration of the new mucous membrane, and should, therefore, be condemned in every instance, except in those cases in which all damaged tissue can be immediately removed by curettage. If, on the other hand, the case be seen later, and the symptoms—such as high temperature—seem to warrant the belief that the germs have penetrated deeper than the free surface of the decidua, involving the lymphatics of the uterine walls or extending to the peri-uterine lymphatics, resulting in a general pelvic lymphangitis or septic peritonitis, no time should be lost, as here intra-uterine irrigation of itself can accomplish no good; but curettage and opening of the cul-de-sac should be resorted to, and the widest possible field for drainage obtained. In this condition, intra-uterine irrigation with antiseptics may be employed, as it is always to be followed by curettage. The technic should be as follows: The vulva should be scrubbed with soap and shaved; the vagina thoroughly cleansed with prolonged douching with bichloride of mercury, 1-5,000. The patient should then be anesthetized and placed on a table in the lithotomy position, the surgeon in the meantime having thoroughly cleansed his hands with the same scrupulous care that he would if he was going to open the abdomen. All instruments and gauzes and all other material to be used having been likewise sterilized, he should proceed as follows: A medium-sized perineal retractor should be introduced into the vagina, the perineum held back, and the cervix exposed; this should be grasped with dull forceps and great care should always be exercised that this is not used in such a way as to lacerate or wound the tissue; by this means the cervix is brought forward and the uterine canal straightened. The largest size return-flow intra-uterine irrigator which will pass the cervix should then be introduced and carried to the fundus, care being taken to avoid wounding of any tissue. The uterine cavity should then be thoroughly washed out with a 1-6,000 solution of bichloride of mercury, from one to two gallons being employed. This should be immediately followed by the introduction of the largest size sharp curette that will pass the cervix and the whole uterine cavity thoroughly curetted, all remains of mucous membrane being removed. The uterine cavity should again be thoroughly irrigated with not less than one gallon of normal salt solution or a 2-per-cent. solution of boracic acid, after which it should be thoroughly mopped with dry sterilized gauze sponges and all débris removed. Hemorrhage during this process may have been quite free, but this should be ignored. After the uterine cavity has been thoroughly cleansed it should be packed with 10-per-cent. iodoform gauze. According to the size of the cervix, strips of gauze from four to ten inches wide may be selected; these should be carried well up to the fundus and the uterine cavity thoroughly packed from above downward, the ends of the strips being cut off and left hanging in the vagina. The forceps still holding the cervix, a fold of mucous membrane should be caught up, just behind the cervix, and a transverse incision about one inch in length made in it. From this time on all cutting instruments may be dispensed with. The finger, separating the tissues passing over the posterior surface of the uterus, is passed up and boldly pushed through that portion of the peritoneum forming the floor of Douglas's cul-de-sac. This will usually be followed by the escape of a considerable quantity of blood-serum; the index finger of each hand should then be introduced into the opening and the incision stretched laterally, as far as the side of the

cervix; as the hemorrhage will be slight, nothing more than torsion of forcep pressure will be required. The patient should be lowered to the Trendelenburg position, and the wound thoroughly sponged clean. A gauze sponge, with tape attached, should then be carried up through the opening under the intestines, which will have already receded from the pelvic cavity so that they will give no further trouble; one or two fingers should be introduced through the opening, carried well up behind the broad ligaments on each side, and the ovaries and tubes freed of adhesions. If pus tubes should be found, they should be opened and drained, and the widest separation of all tissue structures and lymphatic spaces should be secured.

At this point of the procedure, our manipulations should be done with a great deal of care, and we should not be content until every organ in the pelvis is freed from adhesions and is in a position to be thoroughly drained. When this has been secured, the peritoneal cavity thus opened should be thoroughly mopped dry with sterilized gauze sponges, but no irrigation should be permitted. The cleansing having been completed, the sponge introduced to hold the intestines up may be removed and the peritoneal cavity packed. This should be done by carrying up strips of 10-per-cent. iodoform gauze into the peritoneal cavity to a level with the broad ligaments—one or more strips on each side being used—and the entire cavity filled, the ends of the strips being left long and hanging out into the vagina; after which the vagina should be packed with iodoform gauze and a proper dressing applied. Should the temperature immediately become normal, the uterine packing should be removed the second day and not re-applied; but if the temperature should continue a second dressing may be necessary. The cul-de-sac packing should be left from three to five days, when it should be removed and renewed, very lightly; this should be changed from time to time until the healing is complete. The iodoform here introduced immediately undergoes disintegration in the presence of the discharges from the tissues and free iodine may be found in the urine within three hours; the infected field will nearly always become sterile within twenty-four to forty-eight hours; moreover, the infected area is limited and the most abundant drainage secured.

In cases of grave sepsis—in fact, in cases not so grave—I believe it to be always advisable to precede this operation by an intravenous transfusion of from 500 to 1,000 c.c. of normal salt solution. The subcutaneous use of salt solution may be somewhat easier to apply, but it is by no means as useful and in my opinion should not be depended upon to the exclusion of the intravenous method which I usually employ in all such cases. In the general practice of this State I believe this method of the administration of normal salt solution has not become popularized, and for this reason I will here describe the technic I usually employ. All that is required is a glass percolator with a rubber tube attached, the lower end of which is provided with a stopcock, and a small metallic cannula, of the required size to be used in a vein, fitted to the lower end of the rubber tube.

The salt solution should be prepared by boiling chemically-pure chloride of sodium in distilled water for not less than fifteen minutes. This should be cooled down to about 105° to 110° F. and should then be poured into the percolator, after it and the rubber tube have been sterilized with $^1/_{2000}$ bichloride of mercury solution and washed in sterilized water. The percolator should then be lifted three or four feet above the patient's arm, the anterior surface of which has been previously sterilized in the usual way. A rubber tubing or any other ligature should be drawn loosely around the arm above the elbow, causing the vein to stand up prominently. The medium basilic vein (or, if this is small, the basilic) should then be selected and an incision made along the side of, but not over, the vein; the skin is retracted, the vein comes prominently into view, a few touches of the scalpel liberate the vein from its loose connective tissue surrounding, and without difficulty it is elevated from its bed. A catgut ligature should be placed around the vein at the lower end of the incision and tied; a second catgut ligature should be placed around the vein at the upper end, but not tied. The cannula, which has already been sterilized by boiling, is attached to the end of the rubber tubing, the stopcock opened, and the solution freely allowed to flow; this will at once empty the tubing of any collection of air; the stopcock should then be turned off until only a slow dropping results. A transverse incision should be made into the vein and the cannula introduced while the solution is still flowing; the cannula being carried up above the level of the upper ligature, which is then tied firmly around it and the transfusion allowed to proceed.

Time will not permit me to discuss the merits or demerits of other methods of treatment, but it suffices to say that if the plan of treatment here recommended be thoroughly and conscientiously carried out, I believe that there are very few cases of puerperal infection which may not be radically and permanently cured in a very few days. The few cases that will not yield to this kind of treatment will be those in which it has been delayed until general purulent peritonitis has set in, or metastasis to some other locality has resulted; or a few cases in which some other mortal ailment —as endocarditis—is present.

I am of the opinion that this plan of treatment is somewhat different from that usually employed in this State, but I would not desire it understood that I am in any way responsible for its introduction, but believe so far as I am able to learn it is due to the labors of Dr. W. R. Pryor of New York. To those who may desire to pursue the subject beyond what I have been able to say in this paper, I would certainly recommend his admirable little book, "Treatment of Pelvic Inflam-

mations." I believe the method to be perfectly safe. It requires no elaborate outlay of surgical instruments and no special surgical skill. From this time on I shall expect it to be extensively employed and will confidently look forward to a marked reduction in the mortality from puerperal infection.

GENERALIZED VACCINIA.

BY JOHN H. HUDDLESTON, M.D.,
OF NEW YORK.

There have been reported from time to time during this century cases of this eruption following vaccination, and I have collected and tabulated all obtainable reports of cases so named.

It appears that the name has been applied, not to supernumerary vesicles, but to an eruption which is composed of elements which pass through the successive stages of papule, vesicle, and pustule, in the same manner as those produced at the site of inoculation, which comes on some short time after vaccination, and which is diffused more or less over the body. Supernumerary vesicles are found in a small percentage of cases near the site of the original vaccination, but they are usually attributed to inoculation of the virus at the time of vaccination or later into an unnoticed lesion of the skin.

The cause of generalized vaccinia is disputed. Certain authors claim that every case is an auto-inoculation; usually, however, auto-inoculation produces one pustule or very few pustules, and such cases are not spoken of as generalized vaccinia. When, however, the skin is eczematous, auto-inoculation may produce an almost unlimited number of pustules over the affected area and such cases are frequently reported as generalized vaccinia.

The cases tabulated number fifty, twenty-five males, fourteen females and eleven with sex not stated. The ages vary from three days to sixty-two years; twenty-five are under one year and there are six adults. Twelve were vaccinated with bovine virus, either direct from the animal or preserved, twenty with humanized virus, one with cowpox and one with horse-pox, the last two by accidental inoculation. The source of the virus in the other cases is not stated. In twenty per cent., ten cases out of fifty, the case was not vaccinated in the usual way; eight of the ten came in contact with the virus in a vaccine vesicle on another person and the tenth ate vaccine crusts given intentionally in food. This last case was reported in 1809, and I have met no record of any repetition of the experience. Chauveau, however, induced a generalized eruption of vaccinia on horses by giving virus by the mouth, by inhalations, and by subcutaneous inoculations, so that the record of this case may not be scouted without further information. Six of the nine who contracted vaccinia came in contact with it in ordinary daily association or by sleeping with a vaccinated person; one bathed in the same water that had been used by a vaccinated person, and two sucked a vaccine pustule on the arm of another. Four of the fifty were revaccinated and in them the primary vaccination had not caused an eruption; the other cases were all primaries. In four cases the eruption developed before the fifth day and in twenty-eight cases from the fifth to the eleventh day after vaccination. The rest appeared later. Rarely the eruption came out on one day, usually it appeared in successive groups for about a week. One well-accredited case continued to develop the eruption until the forty-second day.

The number of vesicles present varied with the case from three vesicles to five hundred or more, but in each of twenty-four of the cases the number was less than one hundred. In forty-six per cent., twenty-three out of the fifty cases, eczema or other skin disease was stated to be present, and when it was present it was almost invariably the seat of the greater part of the eruption and in some cases it is stated explicitly that the entire eruption was confined to the eczematous area. Seven of the fifty cases terminated fatally, usually with some complication. A closer inspection of the cases with reference to possible etiology shows that in only three is the number of vesicles reported small enough to allow auto-inoculation to be considered a factor unless an extensive area of abraded skin is present. Of cases in which there was such an eczematous area and in which the reporter considered auto-inoculation a cause, there are nine. Of the thirty-eight remaining cases there are still thirteen in which skin disease was present, though in one of these an occlusion bandage was placed over the vaccination at the time it was performed; in two others the reporter stated that from the distribution of the eruption auto-inoculation could not have been the cause, and in certain others the eruption came at a date before the vaccine vesicle was probably ready to furnish material for auto-inoculation. With these thirteen cases omitted, however, in addition to the preceding twelve, there are still twenty-five in which the eruption is not explained by any condition of the skin and in which there are too many vesicles to make auto-inoculation probable, and a diffusion of the virus by the blood- or lymph channels is apparently a necessary explanation.

That the presence of eczema or other skin disease does not in itself constitute a marked predisposition to generalized vaccinia is shown by daily experience, and especially by the experience at the Hôpital St. Louis in Paris where for several years all the dermatological cases were vaccinated and yet but one case of generalized vaccinia appeared. The diagnosis, usually easy, may be extremely difficult; in ten of the fifty cases the diagnosis was confirmed by taking lymph from a vesicle at a distance from the original vaccination and inoculating it on a child or animal or both, and finding that a typical vaccine vesicule resulted. Inoculation on a calf of the matter from a variolous lesion produces little or no effect. The mother of one of the

proved cases had varioloid while the child's eruption was flourishing; that case and two others were considered variola until proof to the contrary was produced. Differential diagnosis must be made in some cases also from varicella, pustulous syphilides, milaria (Martin), the pustular eruption of bromides (Crocker), impetigo contagiosa, and the vesicular eruption which sometimes follows vaccinia. This last ground of confusion I have not seen mentioned, but it is illustrated by the following case, for which I have to thank Dr. F. S. Fielder.

A boy, H. J., eleven months old, was vaccinated with Health Department virus and the vaccination ran a normal successful course. On the third day a few "spots" appeared on the skin; on the fifth day Dr. Fielder saw the case and noted an eruption on the face, neck, arms, legs, and trunk, especially across the lumbar region; it consisted of small discrete vesicles on a base of papular or erythematous character. The vesicles were $^1/_{16}$ to $^1/_8$ inch in diameter, high and full. There was no eruption in the mouth. On the sixth day the case was seen by several physicians in consultation, and by them it was called vaccinia; it was also seen by some diagnosticians of the Board of Health and by them was called varicella. Some of the lymph was collected on this day. On the eighth day many of the vesicles were pustules. No umbilication was seen. The lesions kept on appearing a few at a time until the twenty-second day. There were three other children in the family none of whom had had varicella, and none developed it either before or after the vaccination. Four children were inoculated with the lymph taken from the vesicles, and neither a vaccine pustule nor varicella followed. The eruption was, I think, a vesicular eruption, which exactly like a roseola or an urticaria, sometimes follows vaccination just as all three sometimes follow antitoxin or drug administration. An added reason for this conclusion is that the eruptions of the roseola type may come on in the first three days, vaccinia usually not. The resemblance may be extremely close and the final test in any case is inoculation.

A MASSAGE ROLLER FOR THE APPLICATION OF HEAT OR COLD, COMBINED WITH ELECTRICITY.

BY ROBERT COLEMAN KEMP, M.D.,

OF NEW YORK;

INSTRUCTOR IN SURGERY, NEW YORK POLYCLINIC MEDICAL SCHOOL.

IN THE MEDICAL NEWS, New York, May 12, 1900, there appeared an article by me, entitled "A Metal Roller Water Tank for the Application of Heat or Cold." The instrument which is now presented is a slight modification of the one then described. On the handle of the new roller, there is a binder for the attachment of one of the poles of an electric battery. The present instrument is also more durable in construction than the old model. It is, in effect, a closed metal cylinder, about three and a half inches long and one and a third inches in diameter, revolving on axles, as demonstrated in Fig. 1. One of the axles is a hollow tube and through this the cylinder is filled with water by means of a small funnel. The axle is closed by a screw cap, furnished with a washer. It can be filled with hot or cold water, and thus applied to the patient, or it can be attached to one pole of a battery and employed in combination with electricity, or electricity can be used alone.

I have attached the roller to the negative pole of a faradic battery and the sponge to the positive pole, and secured excellent results in sciatica. On the other hand, two rollers can be employed with a single battery by attaching one to each pole, as demonstrated on a patient, see Fig. 2.

Naturally, the strength of the current in the two rollers is unequal when they are thus employed, but this can be obviated by regulating the battery so that the desired strength is secured in the roller attached to the weaker pole when

using massage with it under moderate pressure, while the pressure with the instrument attached to the stronger pole is made rather lightly. With the assistance of the patient and by the above method the result desired can be readily obtained.

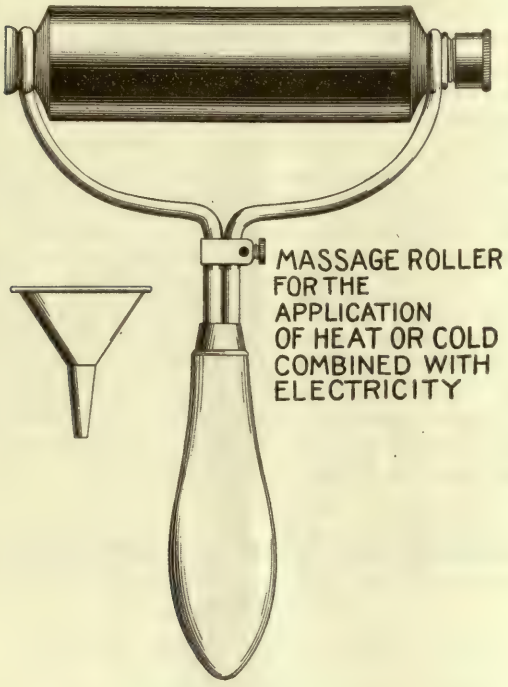

Fig. 1.

This instrument will be found to be of considerable value as an adjunct in the treatment of many conditions. In some cases heat or cold may alone be employed; in others electricity may be combined with them.

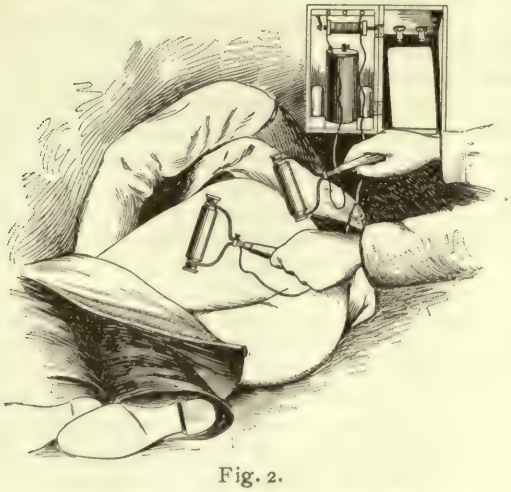

Fig. 2.

The general indications may be mentioned in brief: Alternating heat and cold, combined with electricity, can be applied to the spine, as for neurasthenic conditions, etc. A similar application could be made to the abdomen for chronic constipation. Fig. 2 demonstrates the method of attachment of the rollers. Cold can be employed for headache, heat for sciatica, muscular rheumatism (as stiff neck), lumbago, neuritis, intercostal neuralgia, rheumatic joints, etc. Hot massage for counterirritation may be applied over the kidneys in acute congestion and for oliguria. Electricity combined with heat has proved of even more value in these conditions, the roller being applied over the lumbar region of the cord, as well as over the kidneys. The faradic battery is connected with the instrument. This may seem a novel procedure, but clinically this method has been found to be a valuable adjunct in promoting diuresis. The addition of electricity seems to increase markedly the counterirritation and reflex stimulation, produced by the heat.

The hot roller can also be employed over the thorax in acute bronchitis, etc., as a counterirritant. If it is desired to use moist heat, the part can be covered with thin flannel wrung out in boiling water and the roller then applied over this.

To employ dry heat the best effects produced are by lightly skimming the surface with the instrument. It may be passed over a thin linen handkerchief, if the patient be especially sensitive.

The roller filled with boiling water is of considerable value for the purpose of inunction. Ointments made of lanolin can thus readily be rubbed in, as mercurial ointment in syphilis, or ichthyol ointment in rheumatism, etc. To avoid damage to the instrument it should be lubricated with olive oil which does not readily amalgamate with the oinment. It can be readily cleansed in boiling water.[1]

A CONSIDERATION OF HEMORRHOIDS.[2]

BY JOHN TURNER, JR., M.D.,

OF BALTIMORE;

PROSECTOR OF ANATOMY AND INSTRUCTOR IN OSTEOLOGY, UNIVERSITY OF MARYLAND; PHYSICIAN TO COURTNEY SCHOOL HOSPITAL; MASTER OF PHYSIOLOGY AND HYGIENE IN BOY'S LATIN SCHOOL.

THE rectum in the male is in relation in front with the trigone of the bladder, the seminal vesicles and the prostate gland, and in the female with the vagina and cervix uteri. The lower three or four inches of the rectum is uncovered by peritoneum. It is freely supplied by blood-vessels; the superior hemorrhoidal being the chief branch of supply, and the inferior and middle hemorrhoidal arteries completing the blood supply of the anal orifice, sphincter and skin about the anus. The communication between the two superior hemorrhoidal vessels is free, but they do not anastomose with the middle and inferior hemorrhoidal. The superior hemorrhoidal vessel passes down in the meso-rectum, and divides into two branches, each of which forms a loop on the side of the bowel about five inches above the anus. From these loops a number of vessels are given off which pierce the muscular

[1] The massage roller, with or without the binder for battery attachment, can be secured at the instrument store of James Dougherty, 409-411 West 59th. Street, New York.

[2] Read before Medical and Chirurgical Faculty.

coat and run down immediately beneath the mucous membrane to the anus. The veins have much the same anatomical arrangement as the arteries.

On each side of the rectum is a fossa called the ischiorectal fossa. It is two inches deep, pyramidal in shape and filled with fatty tissue. There are very few blood-vessels in this fossa, yet it is the common seat of abscesses and fistulæ.

The rectum begins at the left sacroiliac symphysis and ends at the anus. It is eight inches long. Some books describe the rectum as beginning opposite the third sacral vertebra, thus, allowing it no mesorectum. Frequently, the rectum is much dilated just above the anus. Large accumulations of waste products in the lower rectum have led to queer diagnoses. For our present purpose of describing hemorrhoids the mucous membrane and veins are the principal factors of cause and effect. The walls of the rectum differ from the rest of the larger bowel in presenting perfectly smooth walls marked by no sacculi, by no longitudinal muscular bands, and by no fatty appendices. The mucous membrane of the rectum is thicker than that of the rest of the large intestine. Certain folds, chiefly longitudinal in direction, are seen in a lax state of the tube; these disappear when it is distended. There are three oblique semilunar folds, which project into the lumen of the tube; one in front by the prostate gland and two others higher up; the latter are to the right, the former to the left. These folds when packed full of hard fecal matter are apt to sag and press too heavily upon the venous trunks, thereby making possible a pile by retarding the return flow of venous blood through these proper venous gutters or drainers of the rectum.

Congenital malformation of the rectum are not infrequently found, which have considerable to do with the presence or absence of piles. A rectum may be imperforate; or it may open into the bladder, or. more rarely still, it may open into the vagina. Sometimes the anal orifice, though present, is so small as to admit only a fine probe.

Hemorrhoids or piles may be defined as small tumors, composed chiefly of dilated veins of the rectum, surrounded by infiltrated connective tissue. It is one of the most ancient diseases known to the profession. The fifth book of the Bible has classed among the incurable diseases "emerods," itch, etc. In these olden times, the presence of piles barred a Catholic from becoming a priest. Piles are divided into internal and external. If internal, or red, they are covered with mucous membrane and are apt to be bleeding piles; if external, or bluish, they are covered with integument or skin, and are apt to be non-bleeding or blind piles.

Etiology.—Biologists find no condition similar to piles in the lower animals, and Darwin held that there appeared to be a natural deficiency in the anatomical structure of the rectum in man. Not so in the lower animals. This, then, leads us to ask, Was man primarily intended to move around on all-fours? However, as we do assume the erect position and, because of the fact that the rectal and portal veins are entirely destitute of valves, simple gravity may be one great cause of hemorrhoids. Anatomically, the superior hemorrhoidal veins in their upward course pass through little slits or openings in the muscular wall and at these constricted places compression is made, thus obstructing (to a certain degree) the free flow of venous blood. This obstruction causes the vein to dilate and consequently varices are formed. Heredity influences their formation as it does that of varicose veins elsewhere in the body. Operations about the liver, where the contracting scar-tissue presses upon the portal vein at the transverse fissure may cause piles. Pregnancy predisposes to piles; so also does overeating, overdrinking, constipation, enlarged prostate glands, enlarged ovaries, congestion of the liver and irregular meals; especially should we remember constipation, which is most frequently the exciting cause. They occur most commonly in middle life—rarely before puberty.

External piles are those little grape-like venous pouches, filled with clot and covered with integument, found at the margin of the anus. They burn, pain, pulsate, irritate and give general discomfort to the patient, especially during and after stool. The diagnosis is easy and the prognosis is good, if operated on early, and if acute in character, usually good, if the bowel is freely opened and kept in that state.

Treatment.—Palliative treatment means little toward curing the patient. In some cases, operative treatment is refused, and then we have to resort to palliative treatment. First, overcome the constipation; this is easily done by the use of confection of senna and sulphur (washed), compound liquorice powder; cascara, or other laxative. Avoid tobacco, wines, whisky, beer, and highly-seasoned food. When there is pain, relief is frequently found in an application of equal parts of extract of belladonna and opium, or belladonna and glycerin to the tumor, and then a hot fomentation should be applied. Leeches applied to the congested part often do good when severe inflammation exists. Sponging the parts with hot water and injecting cold water in the rectum three times a day greatly relieve the patient's discomfort.

Operative Treatment.—For venous piles, immediate relief may be obtained by incising the tumor and turning out the contained clot, and then dusting the parts with iodoform. Before making the incision, the part should be painted over with an 8-per-cent. solution of cocaine. A small piece of cotton should be placed between the lips of the wound if the pile be large, then keep the patient in bed for two or three days. For the cutaneous pile there is no remedy so efficacious as excision; do this even when the tumor is inflamed and edematous, for there is no bleeding which cannot be controlled easily by pressure. Some advise excision by dissection and afterward sewing up the skin. If the ulcer does not

rapidly granulate, stimulate it by applying balsam of Peru or sulphate of copper. Confine the bowels for a day or two and keep the patient in bed. The wound should be dusted with iodoform. Too free incision into the anus may result in a stricture; therefore, due care should be taken not to go deep when excising. Injection of carbolic acid in the pile is, we think, very bad surgery; the tumor thus disappears—by sloughing and destruction of its tissues—an extremely slow process. These injections sometimes cause severe hemorrhages, pyemia, and dangerous rectal strictures. It is rarely curative and is always extremely painful. Dr. Andrews of Chicago reported thirteen deaths from this treatment. The leading proctologists of this country have abandoned its use. Cocaine is most frequently applied as an anesthetic in these cases. Inject well around and over the pile and you may cut deeply and often without any pain to your patient, provided you inject into the skin and not under the skin—a mistake frequently made. The sac after excision should be swabbed out with equal parts of carbolic acid and glycerin; then dust with iodoform or boric acid and a small pledget of absorbent cotton, or iodoform gauze packed in the incision, and over all should be placed a cotton dressing held firmly in place by a bandage. Antiseptic precautions should be observed throughout the whole treatment. A good rule is always to administer a saline purge, preceding the operation, and to irrigate the colon with a normal salt solution just before operating on the patient. The after-treatment consists in keeping the parts perfectly clean and in frequently changing the absorbent dressing.

Internal piles are ordinarily divided into venous, columnar and nevoid. The venous hemorrhoid resembles the external, except that it is covered with mucous membrane rather than skin, and it bleeds easily, especially during defecation. We find this variety most frequently in drinking men and in multiparæ. The columnar hemorrhoid is quite common and is the hypertrophy of the folds of mucous membrane surrounding the anal opening, or the pillars of Glisson. They are red, elongated, and contain a parallel branch of the superior hemorrhoidal artery, hence their redness. The nevoid or capillary hemorrhoid is a small, bright red tumor having a spongy, granular appearance and is found high up the rectum. They bleed on slight provocation and often drain the system heavily. They closely resemble nevoid growths elsewhere. One of the first symptoms is frequent and sometimes constant bleeding, especially increased, however, during defecation. At the beginning the patient loses blood only at stool; later it may occur at any time, resulting in exhaustion and anemia.

I have now a patient under my care, who has to be carefully watched when at stool, for fear he may fall over in a fainting condition and injure himself. The flow of blood is profuse on some occasions. When this is the case, he becomes pallied and unusually nervous.

These piles may protrude and thereby cause a prolapsed rectum. With some the pile tumor may remain protruded so long that they become strangulated, having been caught by the sphincter; or they may inflame and become so congested that their great size prevents their return. The pain in these cases is excessively great. They may become gangrenous, and thus cure themselves by sloughing. These cures are, casually speaking, incomplete. In some rare cases of internal piles urinary disturbances and retention of urine may result from the anal irritation. If there is excessive pain during and after stool you will usually on close examination find a fissure *in ano*.

In arriving at a diagnosis of hemorrhoids, we must sometimes consider polypi, prolapsus ani, malignant growths, such as cancer, venereal warts, and villous tumors; also hemorrhages, pruritus ani and impacted feces may mislead us in our diagnosis. A careful inspection and examination will ordinarily settle the question. The prognosis is good if radical treatment is permitted by the patient. Many think they cannot be cured, and that they must of necessity endure them silently to the grave.

Two or three thousand years ago the itch, the botch, the scab and the rectal tumors (piles) were considered incurable by the Egyptians, who were then skilled physicians. At that time a man with hemorrhoids (and without any idea of antisepsis) was almost isolated. As we isolate cases of hospital gangrene to-day (if such happen to occur) so did they isolate cases of hemorrhoids. They dreaded piles as we dread smallpox.

Treatment.—In mild forms and during the early stage, palliative treatment is successful, but in severe cases, especially when there is much bleeding, nothing but a radical operation will give permanent relief. Avoid constipation; regulate the bowels with compound licorice powder, confection of serra and sulphur, or aloes and belladonna pills, with an enema in the morning. The patient should wash and grease the protruded piles after defecation and then carefully replace them by gentle pressure. The use of some astringent, such as nutgall ointment, will give relief. Regular exercise is necessary. Overeating is injurious, and drinking should be given up absolutely.

Operative Treatment.—The only curative procedure for piles is operative. The two chief methods of radical cure are ligature and the clamp and the thermocautery. Before operating, the patient should be prepared by the administration of a strong purgative the evening previous and immediately before the operation the rectum should be well washed out with two or three soap-and-water enemata. After giving the anesthetic, the sphincter should be stretched by the use of both thumbs till the tension of the muscle gives way. Then one can easily explore the whole diseased area; the pain, after operating is also greatly lessened by this simple procedure. The surgeon, moreover, is not deceived by

"blind" hemorrhage, that is, blood held out of sight of the examiner by the spasmodically contracted sphincter. This overstretching of the anus is a panacea for all nervous diseases, according to some writers. Place the patient during the procedure in the lithotomy position, keeping the knees well apart by Clover's crutch or other means. Each tumor should be seized with small volsellum forceps, drawn down and separated from the subcutaneous and muscular tissue from below with scissors. As the vessels enter the pile from above, there is no danger in separating the lower end of the tumor. The pedicle or stalk should now be tied closely with a strong silk ligature; make sure of the knot holding by employing three half hitches, instead of the usual two. Cut the ligature off short, also the tumor beyond the ligature, enough tissue being left to prevent the knot from slipping. I sometimes pierce the pedicle with a needle and tie in two halves, the superfluous portion being cut off. The ligature has been used for thousands of years—since the time of Hippocrates. The most noted rectal surgeons of the world have employed the ligature for hemorrhoids. Sometimes leeches are used to allay distress before operating.

In using the clamp and cautery the patient is prepared as before, the pile is seized by volsellum forceps, brought down, and clamped tightly with one of the numerous clamps, such as Smith's, Lee's, etc. The pile should then be cut off short about an eighth of an inch in front of the clamp, and the cut surface slowly cauterized several times with a cautery heated to a dull-red-heat. The clamp should then be slightly relaxed and if there is any bleeding, the pile-stump should be again cauterized. Some do not use the scissors in cutting the tumor off, preferring to trim it off with the hot iron.

After either of the operations just described, the parts should be washed thoroughly with an antiseptic solution, dusted with iodoform, and a morphine suppository introduced. Absorbent cotton should also be placed over the perineum and kept there by a T-bandage. One grain of opium should be given twice daily to confine the bowels for three days. Pain may be controlled by the same means. On the third day give the patient a dose of castor oil and keep the bowel well open daily thereafter. If there is difficulty in urination after operation for hemorrhoids, fomentation should be applied over the lower part of the abdomen and the patient asked to make a great effort to urinate. For a few days sometimes a catheter must be used to empty the bladder.

Many operations have been devised to cure these troubles, crushing, injecting carbolic acid, ignipuncture, etc. Dr. Whitehead of Leeds, Eng., has extensively practised and advocated excision of the pile, that is, taking the whole anus from the skin around the anus up to healthy mucous membranes above the pile, cutting it entirely away, and bringing the above circular cut surface down and stitching it to the anal orifice. The great objection to this operative procedure is that it is extremely tedious and bloody, and it may cause anal stricture—a most unpleasant result, which has been called by a famous surgeon (Hall of Edinburgh) the "stigma of a surgeon's art."

AUTOTOXEMIA.

BY WILLIAM W. PENNELL, M.D.,
OF FREDERICKTOWN, OHIO.

AUTOTOXEMIA is a condition of the bodily health modified by the absorption of harmful substances from the intestinal or genito-urinary tracts into the blood; poisonous substances originating within the body as the result of either defective metabolism and elimination or fermentative and putrefactive processes, or both, and producing well-defined symptoms.

It is not intended to insinuate that the body is a laboratory from which issue many poisons, nor that it is necessary that all the forces of the body be kept busy, normally, to prevent systemic catastrophes; but it is believed that the natural forces of the body are able to cope with the ordinary influences within and without itself, and that so long as these conditions exist there is good health.

Putting aside every harmful agency not autogenetic, the resisting powers of the body may become weakened by continued assaults from certain materials originating within itself, and, by entering the circulation, doing mischief in distant organs. Often such cases may be seen in the teething of children. Some contend that the results of dentition are simply reflex phenomena through the nervous system, but in my experience the absorption of materials occurring in not a few children increases the amount of solids in the blood which are faultily eliminated and this is the cause of the "reflex" symptoms, such as fever and nervous disturbances which are but the efforts of Nature seeking escape from its tormentors.

Again, we see these symptoms in the child with cholera infantum or in the adult with cholera morbus. The fermentative changes in milk fed to children explain the many infections of the intestinal canal and, because of the various bacterial forms that swarm in such an inviting medium, should warn us to withhold it as long as the alvine discharges are offensive. The names cholera infantum and cholera morbus might easily be eliminated from the nosological lists and names more in harmony with the cause substituted. The use of purgatives, eliminants and antiseptics in perhaps more than usually favorable cases, enables me to say that in twenty-five years I have not had a fatal result in cholera infantum. Not infrequently we see autotoxemia following in the wake of deficient menstruation—foul-smelling discharges, nervousness, coldness of feet and hands, and burning of feet with constipation. In

[1] Read before the Ohio State Medical Society, Cincinnati, May 10, 1901.

such condition good drainage, eliminatives, and support bring about equilibrium of the body.

The manner in which these disturbing influences are evolved is not well understood, but that there is a production of substances in the tissues or in the intestinal tract due to imperfect combustion or to bacterial influence, a few of which are known but many unknown, some of which are highly poisonous, is well recognized.

Many of the end-products of metabolism are poison, and they must either be decomposed or be speedily discharged or their accumulation occasions illness.

The possibility of convulsions and death from autotoxemia, as a medico-legal question, should not be overlooked. It has been my misfortune to witness death from ptomain-poisoning of autogenetic origin in patients whose kidneys were deficient in eliminating power. The constant elimination of intestinal toxins through the urine must in time result in diseased kidneys from the irritation that is engendered, and later on the production of toxemia. Hence, putrefactive and fermentative processes in the bowels, in a subject having imperfect kidneys, are liable to be followed by dangerous symptoms, if the effect of diuretics cannot be obtained.

Unquenched thirst or abstemiousness in the matter of water-drinking will cause the system to drink at whatever fountain is nearest. This in most individuals is the intestinal tract. Under this head it is fair to mention that the accumulation of ingesta in dilatation of the stomach, with its accompanying fermentation and production of a number of acids and gases, may lead to endosmosis of fluids into that viscus. This is a condition opposite to that which obtains in constipation, if we except the periods when Nature sets up a diarrhea to purge herself of intestinal accumulations. Ask your constipated, sallow-faced, pessimistic patient with the odorous breath how much water he drinks and he will tell you he rarely drinks any. He is an object of commiseration. He is a sort of compound engine, using the same fluid twice before its final release. The materials in his jejunum and ilium are liquid and semi-liquid as in the ordinary, well-ordered individual, but down in the colon a gradual withdrawal of the fluids begins and continues until little more than the solids remain. Is it any wonder he has headache, is morbid, has backache, with tender points on each side of the spine, which he imagines originates in his kidneys; and he is more than half right, for those organs are overworked to held keep the body clear of harmful materials. This man takes cold easily, dreads impotence, has palpitation of the heart and gastric distress. He is bilious, having attacks of vertigo; has a muddy skin, and, above all, has a breath like the emanations from a vault. In the female in addition to these symptoms, we find leucorrhea and quite often irregular and suppressed menstruation. And, if either has a phthisical tendency, the toxemic condition increases the asthmatic attacks,and both are, for the same reason, liable to diseases of the skin.

It is well known that dyspeptic, constipated persons are subject to a troublesome erythema as a result of intestinal infection. I remember a boy with an obstinate constipation whose erythema presented the appearance of scarlatina, and a woman whose erythema resembled erysipelas more than anything else, yet intestinal treatment readily dispersed the ailments. It is when this annoying skin affection is accompanied with fever that its nature is more perplexing, because neither the stomach nor the bowels present any warning note. A key to the situation is often found in the occurrence of an urticaria which is more frequently neurotic, just as acne and pruritus are toxic rather than gastric. But the most distressing skin affection from intestinal absorption is erythema. This symptom is usually symmetrical in distribution and may present a vesicular character; the urine is scanty, of high specific gravity and contains indican and ethereal sulphates. Its successful treatment requires adequate eliminatives and intestinal antiseptics.

The habit of spirit-drinking not only produces intoxication, but is also the cause of many autotoxemias. It matters not whether wine or other liquors are used in moderation or in excess, the symptoms of toxemia are sure to follow. They express themselves in obscure pains, weakness, inability to sustain continued effort, dyspepsia, diminished physical resistance, and often obesity, all of which are as often ascribed to other causes. These patients suffer from neuralgia—a pungent reproach of the nervous system—which the sufferers call "rheumatism," or are the victims of mysterious chills which are explained away under the term "malaria." In these matters abstinence works the cure which is frequently ascribed to other agencies.

Lithemia or modified gout belongs to this category of maladies. Owing to defective metabolism of the nitrogenous substances the blood becomes charged with morbid materials, principally of the uric-acid group. Remembering that uric acid decomposition is the main source of urea, and that urea is an end-product of proteid metabolism, it is easy to see that when this decomposition fails to ensue the uric acid accumulates in the blood, producing digestive and nervous disturbances—a uricemia— and only differs from true gout in the absence of local symptoms and deposit of urates about the small joints. The effect of this accumulation of uric acid upon the gastro-intestinal functions, upon the urinary secretion and upon the nervous system need not be mistaken, but ought to be typical of other toxic states of the body due to other metabolic defects or to fermentative and putrefactive changes in the alimentary canal. So pronounced are the features of this disease that they are often mistaken for separate difficulties. The dyspepsia, the gastralgia, the lumbar pains, the insomnia, neuralgia, sluggish circula-

tion and mental hebetude might easily be treated for long periods as distinct disorders, but when the lithemic state is observed no easier or more brilliant cures are made.

The time was when biliousness and hepatic torpor were regarded as diminished secretion of the liver. For the most part they are now looked upon as autotoxemias. Some writers maintain that the liver and intestinal wall protect the body against the forces that are evolved by fermentation and putrefaction in the intestines from bacterial action; and no doubt they do for long periods in given individuals. Patients we all have had in whom these processes went on from year to year without producing much inconvenience. But there comes a time when the antiseptic power of the liver and the resistance of the intestinal walls become insufficient or exhausted and the hurtful materials leap across the barriers in increasing numbers, and either find their way into the blood or act reflexly by irritating the nerve-endings in the intestines. The liver as a "detoxicator" is supposed to stand guard over the intestinal tube, discharging its duties by storing, destroying or excreting poisons. No doubt this is, for the most part, true. The very fact that the bile is the natural intestinal antiseptic leads us to the conclusion; but bile readily decomposes when exposed to the air, hence the necessity of keeping the liver healthy in order that its bile may possess its protective power in the highest degree.

Well-marked instances of autotoxemia are to be seen in those states in which jaundice is a prominent symptom. The highly-offensive condition of the feces shows that the antiseptic power of the bile has been withdrawn, the slow pulse, the chills and feverishness being the result of toxins from the bowels and not from the advent of bile into the blood. Likewise, certain states of the bowels supervene when the discharges are very offensive, when it is evident the bile is not sufficient in antiseptic or germicidal power to cope with the forces it is supposed to overcome. These states occur in those individuals who tax the protective cordons of the body to the uttermost. They eat more than they need—more than can be assimilated—and the surplus furnishes the conditions favorable to the resulting toxemia.

The theory of antitoxin is a beautiful one to contemplate, yet its sphere of action is hedged about with conditions. If a person were to continue imbibing poisons or produced toxins continuously, and we had to persist in the use of antidotes and antitoxins, I fear health and immunity would not ensue. Possibly the occurrence of autotoxemia in the lower animals is altogether unknown, especially when they are permitted to choose their own food and surroundings, but in man who has cultivated appetites for dishes that appeal to the taste and sensation alone, where satisfaction solely is sought in gormandizing or in the consumption of large quantities of unnecessary foods and beverages, and these are coupled with late hours or inadequate exercise and perhaps needless exposure, the liver as a detoxicator and the intestines as impregnable walls become physically disabled and perform remissly their sentinel duties.

The treatment of these conditions is foreshadowed in the references to them. Some of the medical brethren I have seen decry the benefits of intestinal antiseptics where plainly demanded and believe they are not practicable. Yet, I have known these same brethren to administer drugs with one purpose in view, and the remedies would bring about results in a far different manner than was calculated, unconsciously to the administrator. Let me refer you to an article which we most all use, but not for its antitoxic virtues as applied to the bowels. However, our intentions do not hinder it exerting its influence in the direction where it is not sent. I refer to the use of creosote in tuberculous patients and the antibacterial effect of this drug in the bowels of such patients whereby numbers of intestinal bacteria which swarm there are prevented from infecting the body and accelerating the general decline, the appetite is increased, digestion is promoted, and nutrition receives a new impetus. This seems to be the sole action of creosote in tuberculosis. There are other remedies that correct morbid processes through avenues which differ from our ideas concerning their action. Water, calomel, resorcin, salol, betanaphtol, sulphate of magnesia, and colonic flushing are agents at our comand to cleanse the body of highly prejudicial materials and also to give renewed vigor.

MEDICAL PROGRESS.

Dysentery in the Philippines.—Dysentery, as seen here, appears as two distinct diseases, writes M. H. BOWMAN (*N. Y. Med. Jour.*, Aug. 17, 1901). Acute dysentery is caused by Shiga's bacillus and does not produce abscess of the liver or ulceration of the colon. Its fatal result is due to inflammation of the bowel, rapid elimination of the watery fluids of the body, toxemia and exhaustion, and it requires from four to twelve days for its termination or crisis. Amebic dysentery is undoubtedly produced by amebæ, but there is also a non-pathogenic ameba which lives in the colon. The dysenteric ameba invades all three layers of the colon, makes punched-out ulcers or ulcers with undermined edges, and may produce liver abscess. It is somewhat larger than the other ameba. This chronic dysentery may show itself as an alternating diarrhea and constipation, without, for a long time, any marked constitutional symptoms. During the periods of constipation there is likely to be jaundice. When digestive disturbances supervene, the patient fails rapidly. The acute dysentery due to the bacillus of Shiga seems unaffected by medicines, and the treatment is supportive until the disease has run its course. Hypodermoclysis and rectal enemata of mild astringents and sedatives are of value. In amebic dysentery, magnesium sulphate is not indicated, but quinine solution effectually destroys

the amebæ. The employment of quinine in rapid, acute, ulcerating cases, however, is fraught with danger, and from the nature of such lesions it cannot be retained long enough to produce beneficial effects.

Adiposis Dolorosa.—This affection, characterized by a more or less widespread but irregular subcutaneous deposit of fat, accompanied by pain, and having no discoverable relation to any coexisting morbid condition, has scarcely been described except as occurring in women. C. FÉRÉ (*Rev. de Méd.*, Aug. 10, 1901) shows that it may occur in men. The condition may complicate muscular asthenia, mental disease, hematemesis, epistaxis. Death may result from pulmonary complications. The deposit of fat may not be accompanied by pain in the beginning; one may follow the other. Probably most of the so-called complicating symptoms are only accidentally associated. Two of Féré's patients were hysterical; two others gave a history of neurasthenia.

Agglutinine and Protective Bodies of the Serum.—It is well known that the views of various observers differ in regard to this subject. Some hold that agglutination is simply a reaction of immunity while others deny the identity of the protective and agglutinating substances. The question can only be settled by parallel researches with respect to these substances as they develop in the body and as they are affected by different conditions. ALDO CASTELLANI (*Ztschrift f. Hygiene u. Inf.*, July 31, 1901) has recently investigated this subject, working with the typhoid and colon bacilli and micro-organism of dysentery. He studies the subject from all points of view. Agglutinating and protective substances behave themselves in a like manner when submitted to various chemical and physical influences. There exists a parallelism between the development of these substances in the living body. In immunized animals at first the serum is richer in agglutinine than is the spleen while the latter contains more protective substances. The blood serum gains these substances at the same time, but loses the agglutinines sooner than the protectives. The serum of an animal immunized against a given micro-organism may possess a strong agglutinating power for another micro-organism without being able to produce an immunity against such. Animals inoculated with a given organism may develop agglutinine in their serum without forming at the same time protective bodies. These results force us to abandon the view that agglutination and immunity are closely related processes.

Enuresis in Children.—Assuming that hysteria in children manifests itself as a rule in monosymptomatic form, M. THIEMICH (*Berl. klin. Woch.*, Aug. 5, 1901) proceeds to discuss the relation between enuresis in children and hysteria. Most children suffering from enuresis, according to this writer, are the offspring of neuropathic parents. The spontaneous disappearance of enuresis or its cure by treatment is often followed by the appearance of other disturbances of a recognized hysterical character. Epidemics of enuresis have been observed in schools and asylums; in these cases, due to imitation, isolation suffices to bring about a cure. In the treatment of enuresis by faradism it is immaterial whether the painful current is applied over the sphincter vesicæ or any other part of the body, provided the child be made to understand that even stronger currents will be used if further treatment be necessary. Subcutaneous injections of strychnine owe their occasional success in the treatment of enuresis not to the drug, but to the suggestive value of its painful administration. As in hysteria, so in enuresis, each unsuccessful therapeutical measure in a given case lessens the value of future attempts at treatment.

Tuberculosis-like Bacilli in Human Feces.—Organisms whose morphology and staining reactions are identical with those of the bacillus tuberculosis have been found by different observers in various locations; thus they have been observed in butter, milk, grass and the feces of a number of animals. Very recently they have been found in human feces by THEODOR MIRONESCU (*Ztschrift. f. Hygiene u. Inf.*, July 31, 1901). He found them in the stools of a typhoid patient. They retained the Ziehl-Neelsen stain and occurred singly and in small group. They were somewhat longer and thicker than the bacillus tuberculosis. Some stained evenly, but others were beaded so that it was quite difficult to differentiate them from that organism. They grew abundantly upon ordinary culture media, developing on gelatin or agar plates in four or five days in the form of white, round, dry colonies. With respect to the staining reaction they retain their color after five minutes immersion in 33-per-cent. sulphuric acid, but on treating with 70-per-cent. alcohol most of the bacilli become decolorized. They are alkali producers. Protracted artificial cultivation deprives them of their tuberculous-like staining properties, but these are quickly regained upon passage through an animal. They are pathogenic for guinea-pigs, by intraperitoneal inoculation, in three to four weeks. This organism is not to be regarded as in any way related to the bacillus tuberculosis.

Action of Urotropin.—According to Nicolaier, the action of urotropin as a urinary antiseptic depends on the freeing of formaldehyde at the body temperature. A. GÖTZL and G. SALUS (*Prager med Woch.*, Aug. 1, 1901) contend that the antiseptic efficiency of urotopin cannot be so accounted for. In a series of experiments they ascertained that at a temperature of 17° C. a 5-per-cent. solution of urotropin will kill the microbe of ammoniacal cystitis, the bacillus coli and bacillus of typhoid. At 37° C. a ½-per-cent. solution will delay fermentation in an exposed urine as well as a 3-per-cent. solution at 17° C. The presence of albumin is immaterial. The power of urotropin to dissolve uric-acid concretions was shown in two experiments *in vitro*. On the internal administration of urotropin in 7-grain doses t.i.d., the freshly discharged urine often

gave no formaldehyde reaction with Jorissen's reagent; intense urotropin reactions were obtained always. The reaction of the urine did not materially affect the therapeutic results obtained.

Actinomycosis.—The somewhat rare occurrence of this disease renders opportunities for research in it doubly valuable. Since the primary investigations of Israel, Bollinger, Harz and Bostroem, most clinicians have regarded the bacteriology of this disease as established. The differences in the morphology of the organisms found by these observers have been very generally ascribed to pleomorphism. The latest researches in this disease come from W. SILBERSCHMIDT (*Ztschrift. f. Hygiene u. Inf.*, July 31, 1901) His results authorize different opinions from those formerly held. He examined bacteriologically seven cases in man and two in swine. Of the human cases one was not diagnosed during life; in three the disease was limited to the lower lacrimal duct; in three the disease ran a typical clinical course. The histories of these patients was carefully recorded and diligently compared with the results of the bacteriological examinations. The streptothrices isolated were inoculated into guinea-pigs and other ordinary research animals and were, as a rule, very little if at all pathogenic for them. He believes that the earlier ideas which hold that a certain streptothrix is specific for actinomycosis are incorrect. A number of different organisms are able to produce the typical clinical picture. It is not always possible to examine the nodules of the excretion microscopically, but even when this can be done the demonstration of microorganisms in them does not establish a diagnosis. Culture methods are necessary and when thus submitted the nodules are found to contain different streptothrices. The production of a pure culture of these is not so difficult as has been held. Aerobic and anaerobic agar and bouillon cultures are sufficient to accomplish this result. Mixed infections are not the rule in human actinomycosis. With our present knowledge it is not possible to differentiate bacteriologically actinomycosis from pseudo-actinomycosis. The greatest number of the organisms found in this disease belong to the streptothrix class, but it is not possible morphologically or biologically to subdivide this class at the present time.

Gold-Beater's Skin Court Plaster as a Dressing for Operative Wounds.—This plaster is composed of isinglass impregnated with a sufficient quantity of salicylic acid to render it aseptic. By a new method the plaster is boiled in cumol for one hour at a temperature of 315° F. E. A. DAY (*Amer. Gyn. and Obstet. Jour.*, Aug., 1901) recommends it because it is aseptic, antiseptic, and impervious to germs; it is then, pliable, transparent, fibrous and adherent; it forms a light dressing, readily removed by the application of moisture. This material can be used when it is desired to approximate the skin surfaces of wounds without sutures.

Nasal Suppuration; Its Causes and Differential Diagnosis.—Up to a dozen years ago little had been done and less written on this subject. To-day at least the foundations of accurate knowledge have been laid. S. HORACE LAW (*Dublin Jour. Med. Sc.*, Aug., 1901) divides the subject into two parts—one, suppurative affections of the accessory sinuses; the other, all other conditions which may produce a discharge from the nostrils or nasopharynx. In children foreign bodies often are the cause of a fetid discharge from one nostril; such bodies may form the nucleus of rhinoliths. Diagnosis depends on the history, unilateral discharge, and on touching the foreign body with a probe or seeing it. Excluding polypi, the only tumors which cause suppuration are malignant. Pus may come from the anterior nares in suppurative conditions of adenoid vegetations; a fetid odor is a common accompaniment. Syphilitic necrosis of the nasal bones most frequently attacks the septum. Among ulcerations, frequent forms are lupoid, tubercular and syphilitic. Abscess of the septum follows injury; and is painful in contradistinction to previously mentioned conditions. Atrophic rhinitis or ozena has a distinct and marked smell; the patient, however, does not appreciate the smell at all. The large open space, adherent crusts, characteristic smell, possibly the sunken bridge of the nose—all tend to facilitate diagnosis. Most writers now hold that polypi are secondary to some form of suppuration in the nose, and not that the former are cause while the latter is effect. In regard to disease of the sinuses the old idea that pain under the eyes denotes antral trouble, pain over the eye, frontal trouble, and occipital headache or pain at the vertex, sphenoidal disease, is regarded as fallacious. Tenderness over the palpable cavities is not invariable, though fairly constant. Symptoms will vary in accordance with the open or closed condition of the normal orifice of the involved cavity. The first step toward locating the diseased cavity is to determine whether the pus comes from above or below the middle turbinate body; in the former case the sphenoidal sinus or posterior ethmoidal cells are the source. An occluded antral suppuration is rare; if present the inner or nasal wall bulges and there is infraorbital pain; transillumination aids in diagnosis and probe function makes diagnosis certain. In acute frontal empyema orbital swelling and protrusion of the eye with intense pain are marked symptoms. In the open form, with pus coming from near the anterior end of the middle meatus, a probe may be passed into the cavity and a cannula introduced, followed by washing.

Pest Toxin.—There are present in the sterile filtrate of pest bouillon cultures certain substances which upon inoculation produce in mice and rats an acute, in guinea-pigs and rabbits a chronic intoxication. These substances have been called "pest toxins" and have been submitted to much much investigation. The latest work in regard to them comes from MARKL (*Ztschrift. f. Hygiene u. Inf.*, July 31, 1901). He shows that the pest bacillus freshly isolated from the animal body and cultivated aerobically in bouillon always produces

soluble poisons. The power of these differs according to the nature of the mediums, the age of the culture and the variety of research animal employed. With increasing age of the culture their power on mice is gradually lost, but this immediately returns when the culture is newly transplanted. By the inoculation of gradually increased doses one can produce a high degree of resistance in research animals, the blood-serum of which if drawn at the proper time is antitoxic to the pest bacillus and is able to immunize animals infected with this organism. The correct time to draw such blood is three or four weeks subsequent to the commencement of the inoculations. If in addition to the toxin inoculations one subjects the animals to a series of infections with the dead bodies of the bacilli a combined immunity both against the toxins and infection may be produced. Here the best time to draw the blood is three or four weeks after the last toxin inoculation and one or two after the last culture injection. Such serum posses no toxic power no matter how soon taken after the last inoculation. By heating the filtrate of pest bouillon cultures to 50° C. the poisonous effect on mice is lost, while it remains for rats, rabbits and guinea-pigs. This shows that the filtrate contains two different yet filtrated poisons.

Treatment of Internal Hemorrhage.—During the past three years subcutaneous injections of gelatin have been used with success in the treatment of internal hemorrhages by Quincke, Wagner and others. A series of these cases is now reported from Kiel by DR. GRUNOW (*Berlin klin. Woch.*, Aug. 12, 1901). The preparation used was a 2-per-cent. solution of gelatin in physiological salt solution; the quantity ordinarily used was 200 c.cm. Among 27 cases, including severe hemorrhages from the lungs, stomach, intestines, bladder, kidneys and aneurisms, but one case terminated fatally. The pain at the injection-site is usually severe and in some instances fever and a urticarial eruption follow, but these accidents are regarded by the author as of relative insignificance. The buttocks offer the most convenient site for the injection of the gelatin solution, as the tension of the loose tissues beneath the breasts differs in the various stages of respiration. The latter site is particularly to be avoided in pulmonary cases suffering from dyspnea.

Infantile Typhoid Fever.—The symptoms run about as follows, writes A. A. STRASSER (*Med. Rec.*, Aug. 24, 1901). Few prodomata, incubation not noticeable by any change of action, no headache, there may be initial convulsions. The fever is the prominent symptom and is more or less erratic. Diarrhea and obstipation are about as frequent as in any other infants' disease. Epistaxis and bronchitis are common. The tongue is only that of any fever; rose spots are not always present. The spleen and liver may be enlarged, but are often found so in other diseases of children. Typhoid may be mistaken for malaria, gastro-enteritis, broncho-pneumonia, tuberculosis or meningitis. Abortive cases are frequent, mortality is less, and convalescence more rapid than in adults. The ideal treatment consist of a modified Brand method of baths, cold packs or alcohol rubs, combined with a modified Woodbridge treatment with salol, bismuth compounds, etc. For constipation calomel, for hemorrhage or meteorism turpentine or ice-water enemata may be recommended. Urotropin will act beneficially on the bacilli-laden urine. When convalescence has begun and not before, tonics are indicated.

Heart Disease and Its Treatment.—The predominence of the heart muscle itself in the clinical bearings of heart disease—excuding septic endocarditis—is emphasized by GRAHAM STEELL (*Quarterly Med. Jour.*, Aug., 1901). It is the muscle of the heart that we can almost alone influence by treatment. Even here our sources may be crippled by toxic degenerations and by mechanical conditions, such as narrowing or thrombosis of the coronary branches. Steell believes that harm is done in heart cases by excessive carbohydrate diet, owing to the congested state of the liver and the resulting crippled state of the organ, the functions of which are probably augmented by a largely carbohydrate diet. For the treatment of gastric catarrhs due to cardiac incompetence twelve or twenty-four hours' abstinence is recommended. The question of digitalis being a factor in the production of the sickness has to be considered. The quantity of urine passed is the best guide as to the administration of digitalis; the drug acts slowly, and when diuresis sets in before the lapse of a certain time it is probably spontaneous and not the result of the treatment. Occasional sharp purgation is especially useful in the face of high arterial tension. Simple rest in bed will frequently induce profuse diuresis with disappearance of dropsy. While tonics and strychnine can be given with impunity, Steell prefers to postpone the use of digitalis until dropsy or an engorged liver indicates its use. Paroxysmal dyspnea specially indicates the use of morphine; where such dyspnea is associated with much tension of pulse nitrites and alcohol will at first give relief.

The Prognosis of Traumatic Hysteria.—By far the larger number of cases are made the bases of personal injury claims, writes PEARCE BAILEY (*Med. Rec.*, Aug. 24, 1901), and it is easily understood why a hysteric is often misjudged. The disease finds expression in physical symptoms, such as paralysis, defects in sight, smell, hearing, etc. The normal sensory stimuli fail to be transferred to association systems, and the patient feels, sees, tastes, smells, etc., without being aware of it, and with a firm belief in his own incapacity. Since such belief is false hysteria deserves to be classed among the delusional insanities. It must not be forgotten that a fixed idea may disorganize the life of an individual as much as a surgical injury, and that it may take root so deep that it can never be gotten rid of. In traumatic hysteria, bad heredity makes the prognosis unfavorable, for instability of nervous func-

tion is the natural birthright of children of the insane, epileptic, alcoholic or other degenerates. In the author's experience, however, many of the victims of traumatic hysteria have as good family records as most people. The older the patient, the more likely are the symptoms to become permanent, especially in the presence of chronic diseases; alcoholism and arteriosclerosis being the worst. In the healthy and well-nourished there is more hope. Monoplegias usually recover rapidly, hemiplegias less rapidly, and paraplegias are most rebellious. Twitchings, hiccough, and choreiform movements are of little significance. Shifting, inconstant anesthesia is of more favorable omen than that which is profound and constant. Blindness and deafness may be serious, but affections of taste have accompanied the mildest only of the author's cases. If, after an accident, a patient could be isolated and cared for properly, he thinks we would hear very little of persistent traumatic hysteria. Likewise it is practically impossible for a patient to recover from this disease while money is at stake, so the longer the litigation is postponed the more permanent are the symptoms likely to be. Nevertheless the money is not the cause of the symptoms, and immediate recovery on receipt of damages is not to be expected. Indirect suggestion, by convincing the patient that he can do things which he thought impossible, is the most efficient treatment.

Origin of Oxalic Acid from Protein and Protein Derivatives.—Whether oxalic acid is a metabolic product, or is found in the urine and feces only as a result of elimination of that which is taken in the food, is considered exhaustively by A. E. AUSTIN *(Boston Med. and Surg. Jour.*, Aug. 15, 1901). This writer concludes that oxalic acid is derived from the carbohydrate group in albumins, presumably through the intervention of glycocoll by a process of splitting through which the remainder is converted to urea—a vital process, though imitated by strong oxidizing agents. Oxalic acid may also be derived from uric acid by fermentative action and oxidizing agents, and perhaps also by vital processes. It is present in many of the organs of the body, and is present in urine after long periods of fasting. It may be classified with acetone and oxybutyric acid as a measure of abnormal retrograde metamorphosis.

Prognosis and Treatment of Hernia in Childhood.—The cure of rupture in children is on the whole easier and simpler than in the adult. Nevertheless such cases are often allowed to go uncured owing to apathy and indifference on the part of parents and guardians. The natural tendency toward spontaneous cure is greatest in the first months of life, and becomes steadily less each year. G. HEATON (*Quarterly Med. Jour.*, Aug. 1901), from a study of over 2,000 cases of rupture before the age of twelve years, concludes that usually cure by a truss may be confidently expected when its use is begun in the first twelve months of infancy; after the age of six or eight years the prospect of cure by truss is very much smaller. Umbilical herniæ in young children are most amenable to treatment; a well-applied pad or truss generally suffices. Where the umbilical cord is dilated into a sac at the navel, surgical interference should be prompt. Femoral herniæ are at the other end of the list as regards treatment by truss; but even in female children this class of hernia is comparatively rare. Social conditions determine the amount of persevering and intelligent coöperation to be expected, and has important bearing on prognosis. Special attention should be paid to digestion, inasmuch as flatulence and irregular action of the bowels put increased pressure on the inguinal and femoral rings. Bronchitis, rectal polypus, a tight prepuce, or any condition which causes straining or crying, is a potent factor in maintaining or even causing hernia. While favoring a trial of properly applied trusses in young children suffering from reducible inguinal hernia, Heaton strongly advises operation after the age of five or six years.

Infection Spread by Domestic Pets.—Communication of anthrax and glanders from lower animals to man has long been established, and we know of the like transmission of scarlatina, diphtheria and enteric fever by cow's milk. On account of the filth engendered, the German law prohibits the keeping of domestic animals in pharmacies. W. B. MEANY (*N. Y. Med. Jour.*, Aug. 17, 1901) gives a resumé of cases of diphtheria in pigeons, chickens and cats, and reports disease resembling human diphtheria in swine, sheep, horses, cattle and dogs. Hair, fur, wool and feathers undoubtedly carry such infection. The plague has been spread by cats, probably caught through their rat-hunting propensities.

THERAPEUTIC HINTS.

Infantile Convulsions.—The chief therapy should be directed to removing the cause. During the convulsion, if there is high temperature, the child should at once be placed in a tepid bath and cold water poured over it. Acetanilid or quinine may be given. In reflex convulsions, especially from colic, a warm or mustard bath is serviceable. This is contra-indicated if there is cerebral disease, or if the convulsions appear at the end of an exhausting illness. Indigestion indicates an emetic or calomel, swollen and tender gums should be scarified, and otitis relieved by puncturing the membrane. The violence of the spasm may be checked by the inhalation of a few drops of chloroform or nitrate of amyl. The general irritability may be diminished by bromides, chloral, belladonna, or cannabis indica. Ice or wet cloths should be applied to the head if meninigitis is suspected. In infants a few weeks old, convulsions are usually due to dyspepsia, and the food should be changed at once. The bromides are useless or harmful in such a condition. —ASHBY and WRIGHT in "Diseases of Children."

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, SEPTEMBER 7, 1901.

IS THE NEW YORK HEALTH DEPARTMENT WHAT IT SHOULD BE?

IN estimating the value of a health department to a large municipality, it is to be regretted that tangible factors whereby its efficiency may be measured are for the most part lacking. We know of no ready means by which, for the time being at least, such a department may be known to be doing its duty in protecting the lives of the citizens who bring it into existence. Modern health board work is largely devoted to prophylactic medicines and the results of lazy and incompetent officials make themselves known only after an appreciable length of time.

There is, however, a flavor connected with hygienic science which, if of the true type, can convince the intelligent citizen of the character of the work being done, and it is with regret that we register our feeling that the health department of this city, taken as a whole, does not bear that stamp of genuineness that we would like to see.

Primarily there is a forced air of clericalism, a dry-rot formalism in the work done that presage political influences. These evidences, combined with the significant fact that the Department has been apparently most signally outdone in its efforts to control the smallpox epidemic, lend more than an air of probability to the sentiments voiced in the *New York Times,* under the caption "The Demoralization of the Health Department."

The writer goes on to say: "Recent changes in the personnel of the Health Department, to its disadvantage, emphasize the fact that the introduction of politics into the administration of the one department which should be forever exempt from such contamination, has created an atmosphere which men who are not politicians and who have no other object in accepting office than to discharge its duties faithfully and skilfully cannot breath with comfort.

"Under President Murphy the office of the board became a rendezvous for small politicians, and what they wanted had more weight than anything recommended by the experts of the department staff. Such conditions lowered the standards of the department rapidly and forced the resignation of most of the self-respecting specialists of the staff. Under President Sexton the conditions are even less agreeable than before. Dr. Tracy's large experience and special qualifications helped to maintain the fiction that the board was what it used to be; but he has had enough, and his retirement makes a vacancy for some such luminous statistician as his predecessor, Dr. Nagle, who, not finding appreciation in his office as head of the Bureau of Municipal Statistics, probably wants to return to his old place in the Board of Health.

"The first business of a reform administration, when we secure it, will be to redeem the Health Department from its present deplorable demoralization and restore it to its original condition as the one division of the City Government which was free from the taint of Tammany manipulation. Perhaps it needs a memorable object lesson in what can happen to a city when its sanitary administration is controlled by professional politicians to emphasize the danger which may at any moment result from existing conditions."

That such an object lesson might result, is possible, but bad politicians working in health department jobs rarely "give themselves away," since the health of a community is in the hands of its physicians rather than in those of a Health Department. May the time soon come when the responsible head of a department, doing the active hygienic work of a city of over three

million inhabitants, will be other than one which the present system now allows; who, if reports are to be believed, has so much knowledge of hygienic science as not to know even the name of the most prominent hygienist that the medical world has ever known.

UNDER the smoke of the tunnel nuisance we fear that our Health Department is making much ado in order to hide other delinquencies of a more important character. That the tunnel is an unmitigated nuisance admits of no question, but that it is inimical to the health and welfare of the citizens of New York and, as such, a proper subject of inquiry by the Department is open to question. While we do not desire to enter a brief for the railroad, nor encourage such an unpleasant condition of affairs to continue, it seems to us more reasonable that the Health Department take up work of a much more practical character. We might suggest, as a single item only, a more efficient supervision of the Street Cleaning Department, as our streets still remain in a filthy and disgusting condition.

BIOLOGY AND COMFORT.

WE have referred before to the plans of the North Side Protective Association of Long Island for ridding a large tract of country of the mosquito—always a menace to comfort and sometimes to health. To carry out this scheme it was necessary, first of all, that a biological examination of the waters of the region should be made to determine just where the mosquitoes are breeding and what means will best serve in the treatment of each spot. This work is one that requires expert knowledge, for in the woodland ponds and by the side of the country brooks there are many "wrigglers" that have nothing to do with mosquitoes, but are easily mistaken for them. Moreover, only the biologist who understands the dependence of the mosquito larva upon its environment and its relation to other organisms can properly indicate the proper mode of treating any breeding-place—whether by filling, draining, petrolizing or stocking with fish and predaceous insects.

It was the good fortune of the Association to have in its territory a biological institute whose organization could be employed for its unusual but still biological needs. The magnitude of the task proposed by the Association appealed to the imagination of the workers at the Biological Laboratory at Cold Spring Harbor; they saw the mutual advantages that would accrue through coöperative work and so the union of forces took place—the North Side Protective Association providing the money and influence necessary to carry on the great mosquito campaign and the Cold Spring Harbor Laboratory providing the technical knowledge and the trained workers to study the biological aspect of the problem of extermination and to make recommendations as to the treatment of each breeding-place. What will remain will then be a series of engineering problems and board of health legislation. The Laboratory has been called upon also to organize the campaign of education by which it is hoped to stir up health boards, property owners and other residents to the danger of mosquitoes and to the need of doing away with local breeding-spots.

We feel sure that the Cold Spring Harbor Biological Laboratory will be amply repaid for the effort that it is putting forth to further the plans of the Association. It will benefit by the carrying out of the plans of the Association as an occupant of the territory from which it is proposed to eliminate the mosquito; but it will benefit also, in time at least, by its relation with a body of influential citizens who will recognize that the work of the biologist is not merely hair-splitting theorizing, but for the most part something more important than that, namely, the discovery of the general laws that govern living creatures. And in the future, as in the past, the discovery of these general laws will inure not merely to the comfort, but to the deepest welfare of the human race.

PROPHYLAXIS, DISINFECTION AND CONTAGIOUS DISEASES.

QUARANTINE and disinfection have hitherto been the chief means employed for the control of the spread of contagious disease. The value of these agents consists in the ability to prevent the contact of the healthy with the infected and the power to destroy the contagium vivum in the surroundings of those sick with contagious diseases. Notwithstanding active measures, however, such affections are common and it behooves us to ask whether the methods or quarantine now in vogue are efficient.

An opinion of their value may be gathered from a study of the results obtained by different methods of quarantine and disinfection when applied to an infectious disease the bacteriology of which is

firmly established. In one of our large municipalities, up to the year 1895, the method of disinfection in vogue after diphtheria had been the time-honored sulphur fumigation. Quarantine methods had been restricted to exclusion from school, which restriction was released when in the judgment of the attending physician the patient had recovered. At this time radically different methods of quarantine and disinfection for this disease were introduced. The system of disinfection comprised (1) the removal of all non-washable goods from the infected apartment and the subjection of the same to live steam; (2) the application of a proper carbolic or bichloride solution to all washable articles, walls, furniture, etc.; (3) in all tenement houses, in addition to school exclusion, the doors of the infected apartments were placarded with a sign denoting the existence of diphtheria within, which was not removed nor the patient released from quarantine until a culture from the throat had failed to show the diphtheria bacillus.

A great reduction in the number of cases was confidently expected. The following is the result, comparing two years under the old system with the same number under the new. In 1893 there were reported 1,672 cases; in 1894, 3,812 cases; in 1895, 4,216 cases, and in 1896, 4,912 cases. The population statistics are as follows: 1893, 996,715; 1894, 1,060,000; 1895, 1,091,646; 1896, 1,129,010. These figures show that the number of cases per 1,000 during these years was as follows: 1893, 1.6; 1894, 3.5; 1895, 3.9; 1896, 4.3. It may be said that the increase in the number of cases reported in 1894, 1895 and 1896 was in some measure due to the application of bacteriological methods to the diagnosis.

Previous to 1895 the methods of quarantine were notoriously lax and the inability of ordinary sulphur fumigation to destroy the diphtheria bacillus is well known, yet a very conservative opinion would be that the newer methods of disinfection and quarantine founded upon a scientific basis had at least failed to reduce the number of cases. A consideration of these figures shows the inability of advanced methods to improve materially the existing conditions, and forces us to the conclusion that if we are to be successful in this conflict other factors must be brought into play.

The production of artificial immunity as a prophylactic measure against bacterial diseases has recently been brought into prominence. The idea, of course, is not new as it has been utilized for over one hundred years with respect to smallpox. Within recent years inoculations have been used to prevent the spread of diphtheria, principally in institutions where large numbers of children are confined. The results obtained have been excellent and furnish much food for thought. Unfortunately the duration of the immunity thus produced is in most cases short, in contradistinction to that produced by vaccination, but still sufficiently long to meet the emergencies of a prevailing epidemic. The extensive employment of preventive inoculation against those diseases with respect to which the same is available cannot be too strongly urged at the present time, for it seems certain that in the future this is to be the most effective agent in the prophylaxis of contagious disease.

Seen from another point of view the singular conservatism of a formal procedure in the mode of quarantining certain diseases is of interest. If the investigations concerning yellow fever have pointed out without peradventure of a doubt the true mode of contagion in that disease, then the conventional modes of quarantine are worse than useless in that they impose heavy burdens on mercantile interests and are laughably inappropriate in fulfilling their function.

If there is no contagion in contact, nor can the disease be communicated by other agencies than by direct transmission by an animal, such as the mosquito, then it were wiser to adopt the standpoint of Dr. Havard who in a recent report says: "The duties of quarantine officers have also become singularly simplified. Since we may assume in practice that the infectious germs do not exist outside of man or mosquito, the disinfection of trunks and baggage on account of yellow fever is no longer justifiable. All that is required will be the examination of the non-immunes within five days immediately following their last exposure to infection, the danger of transmission being from their own persons, and in nowise from their clothing or baggage. Ships, like houses, are liable to harbor infected mosquitoes, and will continue to require fumigation."

Thus, again, is the principle reinforced, that prophylactic science must first know the factors involved in the mode of spread of a disease and not advocate a miscellaneous stenching of the air on every occasion, which is little more than a wild shaking of the arms with blindfolded eyes.

ECHOES AND NEWS.

NEW YORK.

Fire in Williamsburg Hospital.—On Saturday night, August 31, 1901, a fire broke out in the laundry of the Williamsburg Hospital located at the corner of Bedford Avenue and South Third Street, Borough of Brooklyn. It was extinguished by Dr. Dowd, the resident physician, and the nursing staff before material damage had been done.

Disease Among Bees.—State Agricultural Commissioner Wieting is giving special attention this year to the work of the bee-keepers in this State. Up to July 20th the four agents inspecting bees under the charge of the Department of Agriculture have examined 416 apiaries, embracing 13,393 colonies. Of this number 229 apiaries were found more or less infected with black or foul brood and 1,834 colonies were condemned to destruction, or to be treated with such remedies as have been found effective. Were it not for the carelessness and negligence on the part of so many bee-keepers the Department would feel that it could soon suppress the prevailing contagious diseases among bees in this State.

To Fight Malaria.—Physicians in public institutions, hospitals, and asylums will be required from now on to submit reports of all cases of malarial fever that come under their observation to the Board of Health. President Sexton said to-day that from all the reports he had received, malarial fever seemed to be a contagious disease. At a special meeting of the Board of Health, held Monday, the following resolutions were adopted:

"Whereas, Recent investigations have shown that malarial fever is an infectious disease, and can be largely prevented by the adoption of simple precautions, and

"Whereas, It is the desire of the Department of Health to prevent the extension of malarial fever, which now exists in some of the boroughs, to the other boroughs, and to restrict its prevalence in those boroughs where it already exists.

"Resolved, That all public institutions, hospitals, home aslyums, etc., be required to report all cases of malarial fever which come under their observation, giving the name, age, sex, occupation, and present address of the patient, and also information as to whether the attack is a primary infection or a relapse, and the address where the disease was probably contracted.

"Resolved, That all physicians in the city of New York be requested to furnish similar information in regard to patients suffering from malarial fever under their care.

"Resolved, That the circulars of information of the Department of Health regarding 'the causation and prevention of malarial fever' be mailed to the addresses in which malarial infection has apparently been contracted, and also to the addresses from which the cases are reported, when these are different.

"Resolved, That postal cards for furnishing the required data be prepared and forwarded to institutions and physicians for reporting the cases of malarial fever which come under their observation, as is done in other infectious diseases."

PHILADELPHIA.

Bequests to Charity.—By the will of the late Catherine Foley an estate of $15,500 is devised to charitable institutions. St. Joseph's, St. Mary's, and St. Agnes's Hospitals and the Consumptives' Home are among the beneficiaries.

Health Officers Urge Vaccination.—Members of the Bureau of Health claim that the increase in the number of cases of smallpox in this city need occasion no alarm, but they have issued a statement urgently requesting that all persons who have not been vaccinated within the last seven years be immediately vaccinated. Thirty-one new cases and two deaths were reported last week. One of the patients is a nurse from the Pennsylvania Hospital, she having contracated the disease from a patient who had been admitted to the wards.

Defense of the City by Health Officials.—The death-rate of this city, which was higher than that of any other northern city during 1900, is still the subject of much discussion. Colonel J. Lewis Good, Chief of the Bureau of Health, is absolutely certain that the fault is not in that department. He claims that, although the city has largely increased in size during the past twenty years, the sanitary conditions on the whole have improved. The year 1900 was also an unfortunate year for Philadelphia. Neither the house nor street drainage is considered inferior to that of other large cities. The showing thus far this year is much better than that of 1900, notwithstanding the unprecedented hot weather in July. The deaths from typhoid and scarlet fever were fewer in 1900 than in any year since 1880 with the exception of three or four.

Death of a Public Benefactor.—John D. Laukenan, President of the German Hospital and of the Mary J. Drexel Home, died August 30th, aged eighty-three years. The Mary J. Drexel Home was entirely supported by Mr. Laukenan and it is estimated that in this way and by benefactions to the German Hospital he expended nearly $2,000,000.

Cremation Statistics.—The increase in the number of cremations has been quite large during the past five years. Last year the number of bodies thus disposed of was 118 and thus far this year they number 62.

CHICAGO.

New Rules for Hospital Staff.—Warden Healy of the Cook County Hospital has issued a guide for physicians, internes and nurses. He believes in systematizing hospital work in such a manner that everything which

goes on from day to day can be known by him and be practically under his personal supervision. The new rules are as follows: (1) Transfers must be reported immediately to Warden by interne in charge of patient at the time the transfer is ordered by attending man. (2) Notice of emergency service and transfer cases should be immediately telephoned to attending surgeon and the particulars of the case given to party answering telephone. (3) Operation blanks must be filled out each day and filed in the Warden's office before nine o'clock the following morning. Duplicate operation blanks must be left with the Warden every Saturday before five o'clock P. M., for the use of the attending surgeon. (4) The junior surgeon must make the final preparation of patient before operation, both in and out of clinic. The senior surgeon should not be permitted to make such preparations, as it greatly endangers the aseptic result. (5) Instruments, needles, sponges, etc., at operations should be handled entirely by the nurses. (6) Senior internes are directed to comply with and enforce orders and instructions of attending surgeons and physicians as to prescribed treatment for patients assigned to their service, and report to the Warden any neglect of patients by nurses or junior internes. They will pay strict attention to rules governing the discharge of patients before twelve o'clock, noon, each week day. (7) Train cases will be taken to Dunning on Mondays, Wednesdays and Fridays. Ambulance cases Tuesdays and Saturdays. (8) Dunning cases should be reported to the Warden's office the night preceding their discharge.

Physical Tests for School-Teachers.—As a result of one year's trial of the plan requiring candidates for positions as teachers in the public schools to pass a physical examination before receiving certificates, there has been a marked improvement in the physical condition of the applicants. When the new order requiring physical tests was promulgated a year ago, it occasioned much apprehension among students in the public schools and in the Chicago Normal School who were ambitious to become teachers. It was feared that the additional requirements would bar many of the best students from the teaching profession in this country. Instead of discouraging the aspirants, however, it has stimulated them to take physical exercise, and to use greater care in diet. In one year the effect of the plan has been to arouse the young women to the necessity of care for their health. Knowing that this examination was coming, these girls have taken care of themselves. In ascertaining the fitness of women for the important work of molding the plastic minds of children, too little attention has been paid to their physical condition. It is unfortunate that necessity so often leads to physical impoverishment and deterioration in the women who prepare for the vocation of teaching. No profession makes such exacting demands upon physical vitality and nerve force, and it is a fact that patience, cheerfulness and forbearance, essential requisites in the ideal teacher, are not found in weak and impoverished bodies.

Return of Dr. Reynolds.—The Commissioner of Health of Chicago, Dr. Arthur R. Reynolds, has just returned from London, England, where he attended the Tuberculosis Congress, as well as the British Medical Association. Before the latter he delivered an address on typhoid fever, and also told something about the operation of the drainage canal and its effect upon the city water supply. He found that European physicians were familiar with what had been and is being done here, and especially so with the work with diphtheria and vaccine lymph.

Garbage Problem.—In London he investigated the methods of disposal of the city's waste, and found that it was an entirely different proposition from our local garbage problem. It was a rare thing to find in the waste there a vegetable or a piece of meat. He saw nothing but dust, paper, etc. The absence of animal and vegetable matter from the garbage is not due to municipal regulation, but to custom. It showed that the American people were much more improvident than the English. The watermelon rinds, the potatoes, the decaying apples and the spare ribs which litter the alleys here are utilized in London. The English are more interested in tuberculosis than are Americans. Tuberculosis is practically the only thing for which the English examine meat and milk, while in Chicago these articles are examined for a score of things.

Typhoid Fever.—Dr. John C. Neely, Assistant Chief Medical Inspector, recently made a report to the Department of Health, in which he says that of 67 cases of typhoid fever, 11 were found to have been undoubtedly contracted outside of the city, and two others were doubtful. This proportion agrees very closely with the results of previous investigations, namely, that about 18 per cent. of the fatal cases of typhoid in Chicago are contracted elsewhere, and are not due to local causes. Among 54 deaths referred to typhoid fever 9 were clearly caused by other diseases, and 6 others were doubtful. Including these doubtful 6, however, as among the typhoid deaths, the investigators attribute the following as causes of the disease: Bathing in the Lake, 2; eating raw vegetables, 2; drinking untreated hydrant water, 37; and for the remaining 4 out of the total 45 cases no cause is assigned. In this investigation particular attention was paid to the milk and ice supply. Three different milk dealers each furnished milk to two of the homes where deaths occurred, and one other to three of the homes. Ice was furnished to three families by two firms and to two families by another firm. So far as can be learned, no connection can be established between the homes supplied with milk and ice by these firms.

Inoculation Experiments.—No successful inoculations have yet been made to test Professor Koch's recent pronouncement that bovine tuberculosis is not transmissible to mankind. The

only culture of the bovine tubercle bacillus available in the city was so old as to prove inert, and a fresh culture is being made with which, when ready, the test will be renewed. Six volunteer subjects are ready for the test.

Resignation of the Sherman Hospital Advisory Board.—It is said that this Board, composed of Drs. James A. Rutledge, Wm. C. Bridge, and Leonard S. Taylor, has resigned. This is another step in the conflict which has been precipitated by the efforts of the Elgin Woman's Club to dominate the medical staff and conduct the hospital after its own methods.

Experiments of Food Values.—We are reliably informed that professors of Rush Medical College have on foot a series of experiments to determine the effects of different foods upon the mental power of individuals, and it is said that these experiments will be conducted upon students of the Chicago Hospital School, recently affiliated with Rush. The students of this school, which has a large number of defective children, will be divided into classes and restricted to a particular diet for a given period of time until the effects can be noted.

A Playful Suggestion to the Health Department, According to the Daily Press.—"Shall hogs be used as scavengers for Chicago streets?" is an issue which may be laid before the City Council at an early day. The Alderman of the Second ward will introduce an ordinance suggested by Mrs. C. T. Babcock. "I could hardly say," said Mrs. Babcock, "what suggested the idea to me, unless it is the filthy condition of the alleys. The plan I suggest can stand on its own merits. I propose that the city own and permit to run at large a sufficient number of hogs. These hogs should be branded in order to prevent theft and the brand should also show what wards they belong to. I suggest also that the hogs should be branded with the names of the Aldermen of the wards. As fast as the hogs get fat the city should sell them at the stock yards and replace them with hogs that are in poor condition, and in that way produce quite a revenue. But this is not all. I would supplement the city drove by private hogs. I would ask all who could afford to do so to buy hogs for the consumption of garbage."

It would seem from this that the scenes of "Our Mutual Friend," which so upset our readers of Dickens many years ago, might be again enacted in the streets of Chicago. Let us all hope it is a newspaper hoax.

GENERAL.

Health Board in Philippines.—Prof. Paul C. Freer of the general chemical laboratory of the University of Michigan has gone to the Philippines to take charge of a branch of the Department of Health there. He has received a year's leave of absence from the university.

Tri-State Medical Society of Alabama, Georgia and Tennessee.—The thirteenth annual meeting of the Tri-State Medical Society will be held at the Tulane, Nashville, Tuesday, Wednesday and Thursday, October 8, 9, and 10, 1901. The attendance promises to be large and an unusually attractive program will be presented. The railroads will give reduced rates. Those intending to read papers should send title to the Secretary, Dr. Frank Trestor Smith, Chattanooga.

Bequest to a Hospital.—By the will of Mrs. Elizabeth N. Thompson, widow of Dr. Austin W. Thompson, which has just been filed, the sum of $25,000 is given to the Cooley Dickinson Hospital in Northampton, Mass., the bequest to take effect upon the death of Mrs. Thompson's step-daughter.

Tuberculous Houses.—The danger of living in a house that harbors consumptives is illustrated by the fact that of 6,273 patients officially examined by the German Imperial Board of Health 2,177, or 34.7 per cent., belonged to families that included other victims of tuberculosis.

Echoes of the St. Paul Meeting.—In the *Münchener med. Wochenschrift* for August 20th, Dr. Carl Beck contributes an interesting letter describing the incidents of the trip to St. Paul of the special train from New York City.

A Royal Tuberculosis Commission Appointed.—King Edward has appointed a commission to investigate Prof. Koch's tuberculosis theory. The scope of the inquiry is officially said to be whether animal and human tuberculosis are identical; whether animals and humans can be reciprocally infected, and under what conditions, if at all, transmission to man occurs, and the means of combating it. The commissioners are Sir Michael Fostre, Secretary of the Royal Society; Dr. Sims Woodhead, professor of pathology, Cambridge University; Dr. Harris Cox Martin, Prof. J. McFadyean, and Prof. R. W. Boyce. The commission has been granted the fullest powers and facilities and the members have been urged to make a prompt report.

Army Vacancies for Assistant Surgeons.—The examination of applicants for appointment as assistant surgeon in the army has been resumed in Washington and San Francisco, and the army medical boards convened in those cities will remain in session as long as there are candidates to be examined. Seventy-six vacancies in the Medical Department still remain to be filled, and as it is desired by the military authorities that the Department be filled up to its full legal limit as early as practicable, all eligible applicants will be afforded opportunity for examination, and those found qualified will be commissioned at an early date.

Outside Lepers Not Desired in Louisiana.—Applications have been made from St. Louis to Governor Head and the Louisiana Leper Commission for the admission of Dong Gong,

a laundryman of that city, recently discovered to be a leper. The St. Louis authorities declare that there is no hospital or home in Missouri, nor indeed any other in the country save in Louisiana, to which lepers can be sent, and it was proposed that Louisiana accept the Chinaman. Albert G. Phelps, President of the Board of Control of the Lepers' Home, said that the offer could not be accepted. The board frequently received propositions of this kind from various States but had declined them all. "The Leper Home of Louisiana," he said, "is supported by the taxpayers of the State and it would be unfair to allow the home to be a refuge for the afflicted of other States. About a year ago three lepers were discovered in New York. There was no hospital in that State to which they could be sent and the poor creatures became a burden on the health officers. A rich woman of New York offered to support the three lepers for life if they could be placed in the Louisiana Leper Home. Admittance was refused. The care of Dong Gong will be laid before Governor Head who will dispose of the application. I am inclined to believe that the Governor will take the same view of the matter as I do."

Journal of Medical Research.—Under this title the *Journal of the Boston Society of Medical Sciences* will be continued under the editorial charge of Dr. Harold C. Ernst. The journal is devoted to the prompt publication of original investigations in medicine; will be published as rapidly as material accumulates, and is the direct continuation of the *Journal of the Boston Society of Medical Sciences.* The expansion of the latter journal is the result of a demand that it should cover a wider field of medical activity than its name would allow. The journal is supported by the American Association of Pathologists and Bacteriologists, the Boston Society of Medical Sciences, and other sources of strength. The first number contains most of the papers read at the annual meeting of the American Association of Pathologists and Bacteriologists in April, 1901. Succeeding numbers will be published as material accumulates, each containing fifty pages at least. Volumes will consist of about five hundred pages, and when one is completed another will be begun. The journal has been started because there appeared to be wide-spread demand for a place in which the results of medical investigation could be given prompt publication, and the support already promised seems to make its success a certainty.

Quietus to Dr. Caldas' Protective Serum.—Major Havard, Chief Surgeon, says that, as the Yellow Fever Commission regards the experiments with the Caldas serum as demonstrations of its uselessness, the commission has definitely severed connection with the Brazilian expert and will not supervise any further experiments conducted by him.

"Dr. Caldas has all along maintained that he found the yellow fever germ in the intestines," remarked Major Havard to-day, "whereas all the experiments conducted here prove that the germ of the disease is in the blood, people having been directly inoculated by blood infection from a person suffering with yellow fever."

Major Gorgas, Chief Sanitary Officer, made the following statement: "Some confusion has arisen regarding the precise position of the Sanitary Department in connection with the yellow fever experiments. In March of this year the Sanitary Department established an inoculation station at Las Animas for the purpose of inoculating non-immunes—that is to say, giving them yellow fever in order to make them immune. This was not an experimental station, and is not such, the sole object being to effect immunization.

"The Sanitary Department has nothing to do with the recent experiments conducted by the Yellow Fever Commission nor with those conducted by the officials sent by the War Department to investigate the origin and propagation of yellow fever, although it did supply the Carroll commission with mosquitoes.

"The Sanitary Department stands ready to immunize any one who desires to undergo the treatment after the risk has been fully explained. It accepts the work of Surgeon-Major Reed and his colleagues of the Army Commission as final, and does not desire to make further experiments in this direction. No amount of evidence could make more positive the conclusion that yellow fever can be conveyed by the mosquito. The person who submits to mosquito infection, however, stands a better chance of recovery than one who contracts the disease accidentally, as the former has care from the beginning."

The Ant as a Surgeon.—The scriptural advice of studying the ways of the ant in order to be wise seems to be followed among certain Indian tribes. We learn from the *Sun* that from a late adventure among the Passamaquoddy Indians who live on the borders of New Brunswick, Dr. Robert Loud of Boston, who has been hunting in the Maine woods for the past month, believes that the aboriginal inhabitants of America are possessed of a wide knowledge of medicine and surgery, using some methods which may be adopted into general practice with benefit to the public. Late in August while camping on the Micmac River he had the misfortune to cut a deep gash in his leg, which bled copiously and caused him much pain and trouble until he was so fortunate as to receive a visit from Chief Oku, a great medicine man of the tribe, whose fame is known among all the Indians of the Eastern States. The cut was badly inflamed when Oku arrived, but he at once reduced the swelling by bathing his leg with a decoction of elm bark and tying up the wound in fresh clay from a brook. When Dr. Loud

asked the Indian to take some stitches in the cut Oku replied: "Heem no good. T'read heem mak' heem swell up, so be sore. See w'at Oku, heem do."

The chief went to a clearing and returned with a dozen large and very lively brown ants. Then, grasping the two sides of the cut between his thumb and finger and pinching them together, he caused an ant to bite at the edge, putting his jaws through both sides of the cut and closing them as firmly as if they had been in a vise. When he had applied eight ants in this manner he cooly pulled off their bodies, leaving nothing but their heads attached.

"Now heem bin stay there 'til heem sore geet well," said Oku, winding a bandage of soft cloth around the leg and fastening it as neatly as a trained nurse could have done. "In nine day—twelve day, maybe, take off cloth; find heem all well."

Dr. Loud followed his instructions and came out cured. The heads of the ants had held on as firmly as pinchers, and although the insects were long dead, it required considerable force to pull away the locked jaws. Dr. Loud also believes that the formic acid which the ants secrete from their mandibles has antiseptic qualities which are unknown to medicine and proposes to make a few experiments along this line on his return to Boston.

A Biography of Dr. S. P. Moore.—As a result of the Memphis Confederate reunion, a biography has been prepared from records of first instance of one of the most important official leaders of the Southern cause, the Surgeon-General of the Confederate States, Dr. Samuel Preston Moore. This appears in a paper in the *Southern Practitioner*, by Dr. Samuel E. Lewis of Washington, an assistant surgeon in the Confederate service and First Vice-President of the Association of Medical Officers of the Army and Navy of the Confederate States: Dr. Moore was a lineal descendant of Dr. Mordecai Moore, who came to this country as physician to Lord Baltimore. He was connected also with the family of the first Deputy-Governor of Pennsylvania under William Penn, Thomas Lloyd. He was born at Charlestown, S. C., in 1813, and became an assistant surgeon in the United States Army in 1835. He became surgeon with the rank of major fourteen years later. During the dozen years between this time and his resignation from the army he served in many parts of the country, from Oregon to the Gulf, from the Texan frontier to Governor's Island in New York harbor. He accompanied the advance guard of troops that went across the plains ahead of the great emigration of 1840. Prior to this he had been for two years during the Mexican War on the Mexican side of the Rio Grande. For five years before the early part of 1860 he was at the Military Academy at West Point, and in the spring of that year he was sent to New Orleans. Having devoted himself to the service and refrained from political concerns and attachments his biographer says, he found himself at the approach of the great struggle much distressed to determine where his duty lay, his mind being as unsettled as that of the then Col. Robert E. Lee. With the secession of his State he decided to quit the army and he resigned his commission. He went to Little Rock, Ark., in retirement, with some intention of making that place his home."

But Dr. Lewis remarks that the times were not conducive of repose, "and trained officers were urgently required in all departments of the army and navy. Therefore, in response to the persistent appeals of his dearest friends, and from a high sense of duty, he concluded to answer the call made upon him as an officer of recognized merit by President Davis and to accept appointments as the surgeon-general in June, 1861."

The Confederate surgeon-general's records were burned in the fire of the night of the evacuation of Richmond, April 2, 1865, and Dr. Moore's private papers, which had been removed from his residence to a place of supposed safety, were destroyed in a part of the city which was afterward burned. So it may be seen why the material for the biography had to be gleaned through correspondence.

Dr. Moore immediately upon his appointment as surgeon-general set about organizing his department, a task whose difficulty was enhanced by the fact that most of the Southern medical men had had experience only in the home practice of civil life and by the action of the United States Government in declaring all medical goods and appliances contraband of war. This action and the blockade of Southern ports threw the medical department of the Southern military service very much upon its own resources.

"The medical department was constrained to seek in its own forests and fields," Dr. Lewis says, "such substitutes as could be found for the more reliable medicines and to build and establish laboratories for converting them into pharmaceutical preparations in large quantities and arrange them in convenient packages for wide distribution and use; to improvise and manufacture by unskilled artisans and the scanty means at hand, such surgical instruments and appliances as their necessity required and ingenuity could invent, which could not be procured through the so-called underground railroad of the time."

The 1,000 surgeons and 2,000 assistant surgeons in the Confederate army treated, according to estimate, 3,000,000 cases of wounds and diseases, Dr. Lewis says. The estimates place the number of Federal prisoners captured by the Confederates and held in Southern prisons at 270,000, and the number of Confederate prisoners taken by the Federal armies at 220,000. Yet, Dr. Lewis says, the number of deaths among the former was 22,570, while the number among the latter was 26,436, the percentage of deaths in the

Confederate prisons being about 8.3 to a percentage of 12 in the Federal prisons. Dr. Moore instigated the formation in 1863 of the Association of Army and Navy Surgeons of the Confederate States and he established by his encouragement the *Confederate States Medical and Surgical Journal*, which was published during the war.

Obituary.—Dr. William H. Bowlsby died at his home, 170 Van Siclen Avenue, Brooklyn, on Monday. He was born at Ballston Spa., N. Y., in 1828. He moved to Brooklyn in 1873 and lived in East New York. He was a member of the Knights of Pythias for many years and when the uniform rank was organized in 1878 was appointed surgeon of the Brooklyn division. In 1880 he was appointed medical examiner of the insurance department of the order, which place he occupied to the time of his death. In 1889 he was appointed surgeon-general with the rank of brigadier and was commissioned by the Supreme Lodge as senior advisory surgeon-general of the uniform rank for life. In 1898 he offered his services to the Government as a surgeon in the war. He is survived by a widow and three children.

Dr. George H. Day died on Tuesday at Iona Island, near Peekskill. Dr. Day was born in Maine in 1833. He was for several years connected with the New York Hotel, New York. For years he practised medicine in Monroe, Orange County, N. Y.

Dr. J. D. Kielty died suddenly August 28th of heart failure. He was born in Fitchburg, Mass., on June 17, 1858, was graduated from the College of Physicians and Surgeons of Boston and Bellevue Medical College of New York. He was city physician from 1887 to 1893, medical examiner from 1892 to 1899, and a member of the Pension Examining Board during President Cleveland's first term.

Dr. George William Wells, since 1892 Medical Director of the Manhattan Life Insurance Company, died at his home at Richmond Hill, L. I., Monday morning of a nervous disorder contracted in the course of his official duties.

Dr. Wells was born in Tyrone, Steuben County, N. Y., June 5, 1841, and traced his lineage back to a family who came from Normandy to England about 1068.

After studying at Farmer's Hall Academy at Goshen, N. Y., Dr. Wells prepared for a college course under the tutelage of the Rev. Daniel Wells, of that town, and was graduated from Princeton in 1865. He then commenced the study of medicine in the office of Dr. Sayre, and was graduated from the Bellevue Medical College in 1868. He attended the post-graduate lectures in the Long Island College Hospital, where he was later made assistant professor of diseases of the nose and throat under Prof. French. He then became physician to the Outdoor Poor Department of the Bellevue Hospital Medical College for diseases of the chest. He was also surgeon of the old Seamen's Retreat Hospital on Staten Island, and practised for ten years as a physician in this city, and for three years in Brooklyn, and then entered actively upon the specialty in which he was best known, as medical examiner at the home office of the Manhattan Life Insurance Company, in New York.

Dr. Wells was also editor of the *Medical Examiner and Practitioner*, and a recognized authority on problems of life insurance. It was largely his foresight that led the insurance companies to appreciate more fully how much their success was dependent upon accurate physical diagnoses of those who applied for policies, he having been among the first to agitate the selection of life risks. Some of his writings on the effect of alcohol, narcotics, and tobacco have been recognized as medical classics.

Dr. Wells was a member of the American Medical Association, for a number of years Secretary of the Yonkers Medical Society, a member of the New York County Medical Association, and the Kings County Medical Society, for ten years Secretary of the Medico-Legal Society, and he had also been Secretary of the Society of Medical Jurisprudence of State Medicine.

CORRESPONDENCE.

THE CANTEEN AND THE AMERICAN MEDICAL ASSOCIATION.

To the Editor of the MEDICAL NEWS:

DEAR SIR: I am glad that Dr. Wilson took the trouble to notice the letter I wrote you some time ago in regard to the Army Canteen.

When I wrote the communication I was under the impression that the procanteen resolution passed by the American Medical Association at St. Paul voiced the sentiment of the Association, but I find that many reputable physicians, among whom are Dr. Crothers and Dr. H. D. Didama, Dean of the College of Medicine of Syracuse University, deny this and state that instead of being the voice of the majority it was the voice of a very small minority of the Association.

When the canteen matter came before this body in full session, it was tabled by a vote stated as two to one. It was then put into the hands of a committee with the general understanding that it was not to be acted on at that session from the fact that the time had been too limited to judge whether doing away with the canteen was an evil or not. Those in favor of the canteen, however, were not willing to let the matter drop, but managed, near the close of the meeting of the Association, when there were but few members present, to have a vote taken on the resolution. The chairman put it to vote. The ayes were called for but not the noes. He declared the resolution passed. If this be a correct rendering of the matter it puts an entirely new face on the whole transaction.

The press immediately throughout the land gave out that this action of the *minority* represented the sentiments of the Association; so it

is generally understood to this day. So far as I am conversant there has not appeared any protest to this action. The Association is supposed to represent the rank and file of the medical profession and why such a representative body would allow without protest a few medical men to pass a measure, as its own, that had been tabooed by Congress and the Christian sentiment of the country, is strange indeed.

Now let us look at this resolution that is supposed to represent the wishes of the medical profession. It reads thus: "*Resolved* that this body deplores the action of Congress in abolishing the army post exchange, or canteen, and in the interest of *discipline, morality* and *sanitation,* recommends its reëstablishment at the earliest date." Here are three reasons why the canteen should have a place in the army. First, on account of discipline. Of all reasons this seems the most singular, the idea being that alcoholic beverages make the soldiers more tractable than abstinence. The getters-up of this resolution were certainly not posted in regard to the doings of the soldiers in and about Manila while under the influence of strong drink. That was during the reign of the canteen. To lift the veil, here is an extract from an article written by Capt. J. M. Moore. He says: "Men (that is, soldiers) would come to Manila, get drunk, assault defenceless women, abuse peaceful natives, disgrace the whole army and tneir country, etc." An English lawyer, a Mr. Sheriden, who was there at the same time, says: "It was surprising to see the American soldiers patrolling the streets (of Manila) in an intoxicated condition, acting as police officials, for which they were utterly incompetent." Also, "One thing is certain, the soldiers were often in a condition that rendered them entirely irresponsible." These quotations could be added to indefinitely, but this will suffice to show that in place of the canteen being a promotion of discipline it was just the reverse. Nearly all the court-martials were laid to strong drink. Our Commander-in-Chief, General Miles, has no good word for the canteen. He says, "I don't believe the present law should be repealed until it has been given a fair trial." Then look at the testimony of the commanders of the British army. Lord Wolseley, Earl Roberts and Lord Kitchener claim that instead of intoxicants promoting discipline, they do just the opposite and should be banished, total abstinence as far as possible being enjoined.

As to the second reason for reinstatement, morality, those in favor of the canteen claim that it should be reinstated because of its moral influence in keeping the soldiers away from base resorts. This idea has been exploded from time to time as a delusion. I have made an extract from a letter of an officer of forty years' service, *viz.,* Brigadier-General A. S. Daggett (retired). He says, "The canteen stands as a constant invitation to the total abstainer to drink, as a temptation to the moderate drinker to drink more, and as a convenience to the drunkard to load up on beer when he has not the means to obtain anything stronger."

This incident might be subjoined here to show that the word 'morality" has no place when looking at the effects of the canteen. During the Spanish-American war, seventeen young men (all abstainers) from a town in Illinois enlisted in the army. In process of time one was sent back a corpse; the other sixteen came back when their time had expired, all with the drink habit firmly fixed. In other words, they were graduates of the army saloon called the canteen. Is it any wonder that the motherhood backed by the Christian sentiment of the country would protest against this method of making moral wrecks of their sons while in the country's service and after being ground out in the Government morality mill, the canteen, turned loose as a menace to society?

Lastly, that the sanitary condition of the army required the canteen—in other words, that the imbibing of beer was conducive to health. This surely will not bear investigation. There is not a life insurance company of note but asks the applicant, Are you a user of intoxicants? and grades him according to the answer to this question. The idea, however, that any form of alcoholic stimulants is conducive to health is absurd. But I will let another of more ability speak on this question. Dr. N. S. Davis Senn says, "Alcohol as it exists in fermented and distilled liquors is a positive protoplasmic poison," etc. Again he says, "As concerns danger to human life every intelligent reader of the public press knows that the ordinary use of alcoholic liquors by persons claiming to be in health is the direct cause of more suicides, homicides and murders every month than are produced by all the other poisons known to toxicologists in a year." As beer is the national drink in Germany, let us have a little testimony from there. Baron von Liebig says, "It is now possible to demonstrate with mathematical certainty that so far as enriching the blood is concerned, the flour that will lie on the point of a knife affords more nourishment than four measures of the best Bavarian beer." Dr. Binz, professor in the University of Bonn, says, "This flooding the stomach and brain with beer, this daily drinking for hours at a stretch, as is customary among great numbers of the lower and middle classes, I regard as a national evil, whether considered from the hygienic, economic or intellectual point of view. The habitual beer drinker is just as much an alcoholic as the habitual schnapps drinker." A long list of German physicians of note could be added to the list of opposers of beer drinking. Bismarck, the great German statesman, said, "Beer makes people stupid, lazy and incapable."

Of course many will say that I am off the track in classifying the canteen as a saloon. That instead of a saloon it is a place of concourse where soldiers could meet and have a social time, where a library was available to get literature to read, etc. Investigation that has been made from time

to time, however, and has revealed the fact that the post exchange is nothing more or less than a beer saloon with this added feature, that there is a bribe held out to the abstainer that the profits on the sale of beer would be set apart for improved food supply. There was the same drinking, carousing and drunkenness that characterized the ordinary saloon. To show how well this bribe or bait has succeeded, one of the procanteeners stated at St. Paul that there were only five per cent. of the army abstainers, thus making 95 per cent. drinkers. Such a showing, although I think far from the facts, gives the strongest argument in favor of doing away with the Government grog-shop, because not nearly all the soldiers will make the army their home but will when their time expires come back to civil life. Then who would say that these graduates of the post exchange would be a benefit to society?

D. I. MCMILLAN.

Sunbeam, Illinois, August 24, 1901.

AN INTERESTING MEDICO-LEGAL POISONING CASE.

To the Editor of the MEDICAL NEWS:

DEAR SIR: In September, 1900, a middle-aged man, in reasonabl good health and with no apparent motive or suspected tendency toward suicide, accidentally took a swallow or more of insect poison (corrosive sublimate in grain alcohol, an ounce to the pint) supposing he was getting whiskey, and not knowing the difference till the poison burnt his lips. The family at once gave him mustard-water and followed as fast as they could ma make them ready with the whites of egg and milk. Free emesis occurred and continued more or less at intervals for two or three hours, during which time I saw him. The vomiting threw the caustic material into the naso pharynx and through the nose, and made an eschar here as well as in the mouth and throat.

The man became almost immediately stupid, apathetic, somewhat incoherent, and manifested an unaccountable aversion or petulance toward his wife and child with whom he had always been especially affectionate.

Noticing that the condition two days after the accident was not unlike that of a severe burn, both in the local eschar and in the general condition of the patient, I made some explanation to the family of the mania or frenzy occasionally following severe burns, and recommended a careful watch over the patient. Following this suggestion the family enforced a reasonable system of precaution.

The third was the only day the catheter was required, but the general condition continued practically unchanged. On the fifth day the slough was beginning to separate a little on the anterior pillars of the fauces and on the sixth the separation was a little further advanced, but no part of slough was yet fully loosened. During this day, while the nurse was temporarily absent from the room, the patient wandered out, a distance of probably twenty feet, to the porch and shot himself in the right temple, being seemingly dead when the nurse got back to him. It was not known how or where or when he had got the revolver—there were always several about the house, but this one had not been seen recently.

There was life insurance in three fraternities, three of which paid without question, but the fourth refused to pay in full on the ground that the death had been a suicide. In the action to recover from the insurance company—Margaret A. Barber vs. The Knights and Ladies of Security—the jury found a general verdict for the plaintiff. They also returned answers to several special questions in which the fact of chief interest is their finding that the "proximate cause" of the death was the accidental dose of sublimate solution. Their findings were made, of course, under proper instructions and definitions by the Court.

H. L. CHAMBERS, M.D.,

Lecompton, Kansas, August 20, 1901.

PARIS LETTER.

(From Our Special Correspondent.)

PARIS, August 1, 1901.

DR. LAVERAN MADE A MEMBER OF THE INSTITUTE—SANATORIUM FOR LEPROUS PATIENTS—LUMBAR PUNCTURE—NOTIFICATION OF VENEREAL DISEASES — COCAINE INJECTIONS — NOVEL METHOD OF CONSULTATION—BERLIN CONGRESS OF SURGERY.

THE death of Dr. Potain, the celebrated heart specialist, having created a vacancy in the Academy of Sciences, at a recent meeting his successor was chosen. The votes were cast three times as a first ballot gave no result. Dr. Laveran, an army surgeon, professor at the Val-de-Grace, and known for his works on intermittent fever, was elected by 40 votes against 26 given to Professor Richet, the physiologist.

There has been some talk recently in France of founding a sanatorium for leprous patients and a small place called Ronceux, in the Vosges, was chosen. The inhabitants of that part of the country have objected to this though the chances of infection are really small. Several cases of leprosy are to be seen at the St. Louis Hospital in Paris, and there exist down south near the Mediterranean several small foci of leprosy, which has however no tendency to spread. Sanatoria of this nature exist already in different parts of Europe. There is one at Bergen in Norway and the patients are allowed to go about outside the sanatorium. There is another one at Christiania in Sweden, where there are some cases of leprosy. At a discussion held at the Academy of Medicine it was decided to send the following answer to the Minister of the Interior, who wished to have the opinion of that society on the subject. A private sanatorium would be found useful if placed near a region where lepers are found. If this

institution were well supervised by the Government, and its interior working based on the highest sanitary conditions there could be no danger offered to the public health. On the other hand, as such supervision cannot be carried out, it would be well that a report be made out to that effect, showing how this would be best managed.

Still another indication for lumbar puncture has been found by Dr. Tuffier, and this is fracture of the skull. The rachidian fluid is rose-colored in such cases, and blood corpuscles can be found with the aid of the microscope.

A recent decree in Westphalia in Germany declares that physicians should notify the authorities of the existence of venereal diseases. Though this decree has been established in a most praiseworthy spirit, it is diametrically opposed to professional secrecy, and it hardly to be supposed that patients will care to have the nature of their disease confided to every body.

The use of intrarachidian injections as a curative agent is still as much as ever to the fore. Dr. Pierre Marie and Guillain have been treating a case of lumbago in this manner. Only five milligrams were used and eight minutes after the injection the pain had disappeared, the patient was able to walk a part of the day. They tried it also in a case of scapulalgia with no success whatever, and the result was the same with one of subacute rheumatism of the lumbar region. Professor Deboe said in connection with this treatment that lumbar puncture was too delicate an operation to be used as a routine treatment of lumbago. He had, however, found it efficacious in certain forms of gastralgia due to tabes. In one case, where the patient suffered from acromegalia, a puncture was made and thirty cubic centimeters of fluid were evacuated. The pain ceased at once. In another the patient, who was tabetic, was punctured during one of his paroxysms of pain, and was relieved immediately. A radical cure can not however be expected.

In a Paris newspaper the following method of having a consultation with one's doctor was described. A physician, living near the Place de l'Etoile, was called up by his patient, whose child was ill and coughing, and told that croup was feared. The doctor asked a few details as to the illness, and then told the mother to put the child before the telephone and to make him cough. After listening a while the physician said it was only a simple cough and added there was no need of his coming.

Dr. Jayle, the assistant of Professor Pozzi, has just written a letter on his visit to Berlin to attend the Congress of Surgery and his impressions are interesting for various reasons. He said he found that he was no longer impressed as he was the first time; greater progress had been made in Paris whereas in Germany it seemed that surgery was more *in statu quo*. He remembered a few words said several years ago by a Berlin assistant, who remarked that one should go to Paris to see how one should not do, and it could be truly said that this was no longer so; what is more, if it were not that he did not believe in disparaging others, he might return the compliment as to certain things. One thing to be envied, however, was the faculty the Germans have for organizing different methods of instruction; their vacation courses, for instance, should be imitated. Speaking of the Congress, Dr. Jayle was struck by the fact that no operations were performed in Berlin while the Congress was in session, and also that an exhibition of surgical instruments and surgical appliances was established in the building in which the Congress was held. The different instrument-makers are thus stimulated to do better. Dr. Jayle also made a few remarks about the Berlin hospitals. No new ones have been constructed, but the new operating-room at the Moabit is much larger than the old one; at the Charité, the kitchen is a marvel of cleanliness and much better arranged than those of Boucicaut or Trousseau, and yet, Dr. Jayle adds, in culinary matters it is not at Berlin that one should go for instruction. The new Pathological Institute of Virchow is very well planned and quite a number of specimens are labeled in Virchow's handwriting. A new hospital has been constructed at Lichterfelde, near Berlin. So far the surgical and medical wards are the only ones that are complete, but sufficient ground has been bought to erect a hospital containing 400 beds. This hospital is to be used for patients from Berlin as well as from the neighboring localities.

THE BACTERIOLOGY OF PUERPERAL FEVER—PREGNANCY AND TUBERCULOSIS.

E. WINTERNITZ (Tübingen), at the Ninth Congress of German Gynecologists, at Giessen, May 31, 1901, read a paper on the bacteriological considerations and their bearing upon the general therapeutic management of puerperal fever. He said that there are many disturbances of temperature during the puerperium which can not be clinically accounted for with any degree of accuracy as to their cause. In such cases it is very probable that the bacteriologist can by studying the germs contained in the pus or in the lochia at least furnish a satisfactory guide to the etiological factors at the base of such fevers as are accounted for caked breasts, phlebitis and the other commoner origins of a rise of temperature after childbirth. In his clinic at Tübingen he has made a series of observations and has found that out of 141 cases in which later true clinical puerperal fever developed there was no example in which the bacteriological features of the lochia were negative. On the contrary all were so unmistakably positive as to render a diagnosis of threatening puerperal fever in its true clinical form very easy and certain. Furthermore it was fully established that of all the febrile disturbances fully two-thirds were proved to be of the

puerperal type by this bacteriological investigation and the remainder to be due to the simpler non-infectious varieties. A comparison with the reported results of other experimenters in the same field shows their totals to be in the ratio of 63 to 37 per cent. respectively—that, is, entirely confirmatory of the author's statistics. Of the well-known germs, the streptococcus is by far the most common it being found in 63 per cent. of all the cases. Next in line come the mixed infections wherein are found the saprophytic bacteria and the anaerobic bacteria, both not yet very well known, associated with the more purely pyogenic varieties. Prominent in such cases are the staphylococcus and the gonococcus and sometimes the bacterium coli commune. At the Tübingen clinic the therapeutic management is the following. So soon as a bacteriological examination has shown that pyogenic germs are present intra-uterine douches of any of the familiar and reliable disinfectants should be given with the hope of destroying at their very focus the germs and their products. It is a significant fact that they have never yet been able to prove a bacteriological annihilation of the germs. Clinically, however, these douches produce a cleansing and are followed by a decrease of the fever in a manner to show that they certainly have considerable value. Perhaps in the future some germicide will be discovered which will be focally totally destructive to the germs. At any rate it seems certain that no single step is so valuable as a bacteriological examination of the lochia as a foundation of the future handling of the case.

Kaminer, at the Society for International Medicine at Berlin, June 3, 1901, read a paper on the subject of pregnancy, childbirth, and tuberculosis and their mutual influence. His points were that, while the gynecologists were teaching the destructive and unfortunate results of abortion, the physicians were learning the conditions under which induced abortion is not only justifiable but positively indicated as a therapeutic measure. Chief among these may be mentioned the various organic diseases of the heart and tuberculosis, especially pulmonary tuberculosis. The gynecologist desires to limit the measure purely to such cases as are diseased purely in virtue of the pregnancy. Maragliano has gone so far as to claim that every pregnant woman should be deprived of her fruit as soon as any pulmonary focus is discovered. In work in this field at the Senator Clinic and the Clinic for Tuberculosis Kaminer has followed out fifty cases of tuberculosis complicated with pregnancy and found that thirty-three suffered greatly in virtue of their infection both during the gestation itself and at the labor also. The other seventeen women apparently underwent no inconvenience from the complication. Along with the ordinary inconviences of pregnancy (vomiting, lowered nutrition, impeded circulation) there appear in his opinion the deleterious factors of the puerperium much augmented, which he seeks to explain by uterine absorption. Whether in the better classes of society these conditions are wholly ameliorated he is not able to determine definitely. On the other hand, however, he is convinced that an interruption of gestation is the one method of treating these subjects rationally. Of the various means at hand for such a purpose, artificial abortion is the best. With the aid of skilled gynecologists he has carried out this therapeusis eighteen times and found that in twelve of the patients he was able to control and then bring their tuberculosis to a standstill. He further thinks induced abortion to be indicated whenever the first signs of tuberculosis appear during any pregnancy and whenever any symptoms of a lighting-up of an already quiescent process are evident. It is also an important point to consider how to prevent impregnation among the tuberculous.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Section on Medicine.

Stated Meeting, Held May 21, 1901.

E. Franklin Smith, M.D., Chairman.

Anomalous Rheumatism.—Dr. Brill presented a case that had been under treatment at Mt. Sinai Hospital with peculiar rheumatic symptoms. The family history was negative and there was no rheumatism in the patient's past personal history. There had been slight jaundice. The patient denied gonorrhea and syphilis. The joints had not been swollen, but there had been some fever and soreness. There had been a peculiar eruption on the body for several weeks. When the patient came into the hospital the temperature was 100° F. and rose in the afternoon to 103° F. The pulse-rate corresponded to the temperature and its variations. The eruption on the body resembled erythema multiforme. During the course of a day or two in the hospital the patient developed some signs of pleurisy on the right side; a little bit later there were complaints of tenderness over both tibiæ. Swelling took place at the sternoclavicular junction and considerable tenderness was also manifest there. The character of the skin eruption changed and papules were noticed. These resembled erythema nodosum. The blood-count showed that there was distinct leucocytosis, sixteen to eighteen thousand leucocytes were found in a cubic millimeter. Imperfect ankylosis of the fingers occurred as the result of involvement of the joints of the fingers.

Treatment.—Ordinary rheumatic treatment failed to influence the course of the disease. The salicylates seemed to influence the temperature course, but symptoms that seemed to be rheumatic manifestations continued to occur. Blood-cultures were taken and in one out of five of them, with very careful precau-

tions taken to avoid any chance contamination from the skin surface, streptococci were found to exist in the blood. Notwithstanding careful treatment in the hospital, the patient continued to suffer from intermittent fever that sometimes reached 105° F. in height and then descended to normal, only to recur after a day or two. No purulent condition could be found that might explain this seemingly septic temperature. Careful examinations were made of the exterior of the body and of the internal parts that might possibly contain an abscess. After the discovery of the streptococcus in the blood, antistreptococcic serum was administered. Almost immediately afterward the symptoms began to abate. After the injections had been continued for some days, the patient's temperature remained normal and further rheumatic symptoms failed to occur. The patient, who is now in reasonably good health, was presented to the section.

Bacteriology of This Case.—Dr. Libman said that in cultures taken from the blood of this patient he had found a streptococcus. Some time ago Wassermann of Berlin reported that he had found what seemed to be an attenuated streptococcus in the blood of a rheumatic patient under treatment at the Institute for Infectious Diseases, Koch's department of the Charité Hospital at Berlin. This streptococcus grew well only on a special peptone solution. English observers reported only a short time ago that they had found a streptococcus in the blood of a rheumatic patient. The streptococcus found by Libman grew on a solution of serum agar with glucose. This streptococcus when inoculated into the guinea-pig failed to produce any effect. Rabbits inoculated with it were seen to limp after a few days. They recovered completely from it, however.

Cultural Characteristics.—The streptococcus found by Libman grows very well on Wassermann's medium, but is not very tenacious of life when grown artificially. After several generations it failed to be successfully cultivated. The fact that it grows on Wassermann's medium does not stamp it as assuredly of the same nature as the streptococcus described by Wassermann. Dr. Libman has found that practically all streptococci grow well on Wassermann's medium. The streptococcus under observation at Mt. Sinai seemed to resemble the one described by Wassermann in many ways and is of interest because found in a case of rheumatism in which the constitutional invasion and the manifold symptoms pointed very clearly to the fact that the microbe causing the symptoms must be in the blood.

Unusual Human Parasite.—Dr. James J. Walsh presented a specimen of the larval form of tenebrio obscurus. A patient reported that the worm had come from her. As it was a meal-worm and represented the larval stage of a beetle, this scarcely seemed possible. The specimen was forwarded to the entomological department at Washington, which replied that in a certain number of reported cases, though they were very rare, tenebrio obscurus had been found in human beings and occasionally caused symptoms. In this case the patient was using gluten suppositories. It seems not improbable that some of these were exposed and that the beetle laid its ova in them before their use. The heat and moisture of the rectum provided favorable conditions for the development of the larva which eventually found its way out through the anus.

Human Myasis.—Dr. Walsh said that, while scarcely any mention is made of it in the textbooks on medicine, a certain number of winged insects do occur in the larval stages in human beings. There are three or four varieties of flies, the larvæ of which have been expelled from the stomach. Usually the vomiting which causes their expulsion is set up by the irritation of the presence of these parasites. The insects lay their ova in milk or in cheese, or in cooked vegetables that are allowed to stand over, and these are taken into the stomach and there develop into the larvæ of the fly. Occasionally the parasites are passed either in the worm stage, or when already possessed of wings and, as a rule, they do not give rise to any very serious symptoms.

Human Cantharisasis.—In a certain number of reported cases the larvæ of beetles have been found in human beings. It was suggested some time ago by the president of the London Etymological Society that the symptoms which these insects cause should be grouped under the name of human cantharisasis. Both the meal-worms, tenebrio obscurus and tenebrio molitor, whose adult stage is represented by the ordinary black beetle so familiar in our houses, have been found in human beings. It is probable that they do not act as true parasites, but having been accidentally introduced, usually in the ovum stage, they reach their development in the human body and then find their way out.

Human Scholechiasis.—It was suggested that the name scholechiasis should be applied to those cases in which the larvæ of the lepidoptera were found in human beings. Butterfly larvæ have not infrequently been found in the stomach and occasionally in the alimentary canal of human beings. The patients are usually children and the swallowing seems to be accidental. The question of winged parasites in the various cavities of the human body developing and obtaining their nutrition from the human being until the winged stage is reached is a rather large one. A number of such parasites have been found and some of them caused very severe symptoms, especially in the nose and accessory sinuses.

Site of Gastric Cancer.—Dr. Stephen S. Burt read a paper on colloid cancer of the stomach

and omentum. He discussed the question of the location of cancer of the stomach and showed that in more than one-half the cases the cancer occurred at the pylorus. Of the 1,300 cases collected by Welch, nearly 60 per cent. were situated in the pyloric region. Of 91 additional cases that Dr. Burt himself has collected, 47 occurred at the pylorus. Other parts of the stomach seem to have no special aptitude for cancer, except that a large number occur near the esophageal opening. A very remarkable thing is the great infrequency of cancer of the duodenum, which is somehow wonderfully spared from the development of malignant growths.

Colloid Cancers.—Of the 91 cases of cancer of the stomach that Dr. Burt has collected, 12 were of the colloid variety; 4 of these involved the omentum also. In most of the cases the whole of the stomach-wall was infiltrated and yet stomach function was only very slightly impaired. The viscus was able to accomplish its work much better than when cancer occurs at either of the orifices. The stoppage of the flow of nutritional material in orifice cancer soon becomes serious and a vicious circle is set up that rapidly makes the condition of the patient worse and worse.

Diffuse and Localized Cancer.—While in most cases colloid cancer is diffuse, occasionally a localized tumor occurs. In 4 of the cases that Dr. Burt collected there was an extension to the peritoneum. The gelatinous form of colloid cancer has a special tendency to spread to the peritoneal surface. It infiltrates the layers of the gastro-intestinal tract, and then on the surface of the peritoneum may spread to the diaphragm; thence it usually finds its way into the thorax and involves the pleura and pericardium. It not only attacks the peritoneal covering of the viscera, but invades the viscera themselves. Small nodules of colloid cancer may even occur in extensive metastatic cases in the diploe of the cranium. Colloid cancer has an especial tendency to break down and in pus cases a marked, acute cachexia develops. When ulceration does not occur, dropsy develops and is apt to give considerable trouble.

Pathological Appearances.—Even with the naked eye the alvelor appearance of this form of cancer may be readily seen. Within the large alveoli, mucoid material occurs. Most pathologists consider this substance due to a degeneration of cancer tissue. Langerhans, however, considers that this is a specific form of cancer tissue. The neoplasm grows by the accretion of this tissue. The most characteristic alveolar appearances are found in the more recent parts of the tumor. This type of cancer has been spoken of as a reversion to a lower form of tissue, an original embryonic type, but not a true degeneration. On the other hand, this kind of tissue, being very poorly nourished, would show special tendency to ulceration even more frequently than at present, but for the indolent character of the mucous tissue. The mucus is therefore considered a protective provision of Nature.

Theories of Etiology.—For this form of cancer, Conheim's explanation of the origin of such neoplasms seems most suitable. During the embryonal stage of development, bits of germinal tissue, whose nisus generativus had by no means been exhausted, are nipped off from the related tissues in which they lie and become enclosed in neighboring tissues. Later on in life, some injury, or a reduction of the resistive vitality of the individual, excites these germinal cells into activity with the result that embryonal tissue of a special malignant character develops and its secretions, acting as toxins, are absorbed into the general system producing the cancer cachexia. Some pathologists assert that colloid cancer is always secondary and that a primary nodule of cancer will be found hidden away in some organ. They insist that this cancer nodule should be carefully looked for, as it explains better than anything else the origin of the colloid condition. One of the most striking things about colloid cancer is the fact that it is prone to cause almost no symptoms, or only symptoms of the most indefinite character, for a long time. This rule applies especially to the very diffuse forms of the neoplasm. Nodular colloid cancer is more easily recognizable. Some of the difficulties of diagnosis are illustrated in the following case.

Symptomatic Course.—The patient was a man, forty-three years of age, who came in May, 1900, complaining of pain in the right hypochondrium. For some time before he came to the hospital his abdomen was enlarged and his feet swollen. He had suffered considerably from constipation and there were some signs of a decrease in the amount of urine passed. Physical examination of his abdomen showed considerable tension of the abdominal walls and ill-defined fluctuation could be made out. There seemed enough fluid to demand tapping and on the insertion of a cannula 100 ounces of fluid were withdrawn. Notwithstanding the withdrawal of this large amount, there was still a feeling of resistance in the abdominal wall. Sufficient relaxation occurred, however, to enable the examining hand to detect the presence of some tumor nodules. The inguinal glands were enlarged, but the supraclavicular glands were not at all affected.

Repeated Tapping.—The patient's mind continued clear, notwithstanding the progress of the case, and he was tapped altogether some twelve times. Each time over 100 ounces of fluid were withdrawn. Toward the end as much as 250 ounces were withdrawn and the patient had to be tapped every few days. During the course of one of these tappings there came through the cannula some characteristic portions of the tumor. These, when placed under the microscope,

showed at once that the neoplasm was of colloid nature. The patient's mind continued clear to the end and death took place from asthenia. This is one of the few cases of colloid cancer in which the diagnosis has been made before death. There is nothing characteristic about the symptoms by which the diagnosis can be more than suspected, unless, as happened by fortunate accident in this case, some portion of the tumor can be obtained for microscopic examination, when, of course, the diagnosis is easy.

Rarity of Colloid Cancer.—Dr. Beverley Robinson said that colloid cancers are rather rare. He has seen none of the stomach and not more than three of the omentum. The marked tendency of such pathological rarities to occur in groups, is well illustrated by the fact that, just about the time that Dr. Burt's case came under observation, a patient suffering from the same condition entered St. Luke's Hospital. This patient's case is interesting, because the condition was not diagnosed until the autopsy, notwithstanding the fact that an exploratory incision was made.

Colloid Growths and Peritoneal Tuberculosis.—In the case under Dr. Robinson's care, the sense of tension in the abdomen and the evident presence of fluid had given rise to the conclusion that tuberculous peritonitis was present. The patient was referred to the surgical ward, where incision was made and the fluid evacuated, but it reaccumulated again before long. The patient was returned to the medical ward, where he was under observation for some time. In this case there was very little fever, not much emaciation, and the ascitic fluid seemed to be of the ordinary character. At the exploratory laparotomy a number of small tumors of the mesentery were noted, but these were considered to be enlarged tuberculous glands. The feeling communicated to the fingers by the presence of these little tumors is not unlike that produced by tuberculous glands, so that deception is easy in the matter.

Differential Diagnosis.—Dr. Thomas Satterthwaite said that colloid cancer is very rare. It constitutes at most two per cent. of all forms of cancer. Colloid cancer of the stomach is proportionately much rarer than this. The only absolutely sure method of diagnosis is by exploratory incision with the removal of part of the tumor for diagnostic purposes. The postmortem appearance of affected tissues is not unlike that produced by tuberculosis. A number of white glistening bodies are seen, many beneath the serous covering of the viscera, looking not unlike miliary tubercles.

Etiology of Colloid Cancer.—Waldeyer insists that all peritoneal colloid carcinomata are secondary and that the primary nodule of cancer can always be found, if looked for. Pathologists generally do not accept Langerhans's theory that the colloid material is the specific tissue of the neoplasm, but insist on the contrary that it is a form of degeneration. The colloid change in the neoplastic tissue is really Nature's effort at eradicating the neoplasm. The tissue thus lacks vitality and is liable to break down. As a rule, however, the neoplasm has so impaired the forces of the individual that if a suppurative process results, instead of proving helpful, it constitutes another drain upon the patient.

Symptomatology.—Dr. Einhorn said that often the only symptom produced by colloid cancer is a feeling of discomfort. Sometimes even this is absent and loss of flesh is what calls the attention of the patient and friends to the existence of some serious pathological condition. The loss of flesh is, however, not disproportionate to the lessened amount of food which is taken. The appetite is affected rather early in the disease. Needless to say, on examination of the stomach chemically no specific symptoms are found. Lactic acid is not present and there is no modification of the amount of hydrochloric acid. Dr. Einhorn has seen a definitely limited colloid cancer in one case. In all other cases the neoplastic process was diffuse.

Suspicious Case.—Dr. A. H. Smith said that he had under observation at the present time a case in which there was considerable ascites, though there was no enlargement of the liver and very little evidence of kidney disturbance. The urine contains no albumin and only an occasional hyalin cast. On movement of the patient, there is very little change of level. Four weeks ago an attempt at tapping brought away a very little fluid. The sensation given by the trocar was that of contact with something more solid than the intestines themselves. The urine was at times scanty, but this seemed to be due to the intra-abdominal pressure causing inaction of the kidneys. There has recently been a better flow of urine and this was thought to be due to the fact that a neoplasm was present and that somehow the tumor had changed its relation to the renal vessels so that instead of pressing on them as before, it left the circulation in them free. The patient continually grows weaker and is at present in very poor condition. There is a doughy feel in the abdomen, though there is an absence of nodular enlargements. There are no serious gastric symptoms, though the loss of appetite is marked; there is no pain nor vomiting. The presence of colloid cancer is suspected.

Diagnosis Antemortem.—Dr. Burt in closing the discussion said that colloid cancer is very rarely diagnosed before death. Fagge once saw a case when on a visit to the country in which the diagnosis was made before death. It is often said that there is no fluid in the abdomen in these cases, but ascites is sometimes one of the prominent symptoms. This is especially true if the tumor does not fill the abdomen. Pepper reported a case in which intra-abdominal pressure became very high as the result of the accumulation of fluid. In one reported case colloid material was vomited. When the tumor grows large and the ascites is also a marked feature of the case, the urine is apt to be very much reduced in amount. This will soon produce uremic symptoms, unless

the pressure is relieved by tapping. Other important functions will also be interfered with because of the disturbance of circulation due to the intra-abdominal pressure.

Intracranial Neoplasms and the Neurons.—Dr. F. Savary Pearce of Philadelphia read a paper containing some points of intracranial neoplasms considered from a neuronic standpoint. Dr. Pearce said that cerebral neoplasms are rather frequent. The neoplasm could have been removed by operation in about 7 per cent. of the 600 cases studied by Dr. Starr. Differential diagnosis as to the location of tumors is extremely important from an operative standpoint; therefore, if points for diagnosis can be gleaned from the neuronic theory, they would be very valuable. Rapidly growing tumors produce a condition of shock, with consequent retraction of the neurons. Slow growing tumors do not produce shock and consequently many of the acute localizing symptoms are missed.

Functional Symptoms.—Most of the hysterical symptoms have their only rational satisfactory explanation, if one accepts the theories of separation of the neurons and of their wrong connection at times, because unaccustomed nerve-endings are in contact. There is a perversion of neuronic activity with consequent disturbance of sensory impulses. Galvanism of the scalp, as is well known, may cause headache. This seems to be due to the fact that sensory neurons are interfered with and in consequence of their irritation their endings are pressed close together, as when irritated, and this is translated into pain.

Sensory and Motor Disturbances.—Sensory and motor pathological phenomena are best explained as perversions of neuronic activity. When there is the sensation of subjective noise in the ear, as in the oft-complained-of tinnitus, the basis of the disturbance would seem to be a lining up of the neurons that usually conduct sounds, but without the ordinary external stimulus of noise to produce the lining up. In such motor phenomena as chorea, it would seem that there was an active disturbance of the motor neurons, with a consequent production of involuntary motion.

Theory of Neuronic Motion.—Dr. Charles L. Dana said that if by the neuron theory is understood the separation of the dendrites of nerve-cells from the end-brushes of nerve-cells, the discussion seems futile, because this theory is not supported by any biological evidence except in some very low animals. It is only a conjecture, the foundation of a theory that may serve for pleasant hypotheses. It is true one may consider that tumors may push apart neurons and so cause symptoms. The idea is grossly material, however, and does not add to diagnostic power.

Advances in Brain Tumor Diagnosis.—There are some recent advances in the diagnosis of brain tumors that are worth discussing. Examination of the blood may throw some light on the nature of the tumor. Marked leucocytosis shows that abscess or inflammation is present. More leucocytes are found in the blood in sarcoma, than in carcinoma. There are some diagnostic advances that seem to point to the fact that the eosinophilia may be of diagnostic aid. Stereognosis is absent when the cortex is slightly affected in the motor region. This symptom is of more significance than is the anesthesia. Babinski showed that the flexor response of a large toe occurs when there is a lesion of the motor cortex or of the pyramidal tract.

Tumors and Neurons.—Dr. Sachs said that even the smallest of brain tumors compared to a neuron was as a giant to a pigmy. The growth of tumors could therefore not be expected to produce any very definitely localizing symptoms, because of interference with the functions of special neurons. Too many neurons in the neighborhood of a tumor were affected by it for this to be expected. While the retraction theory of the neurons is popular in Philadelphia, it does not meet with very general acceptance, or approval, in other places. There is no substantial proof that neurons do actually move during life and their supposed movement is a mere speculation that gives a quasi foundation to a number of interesting theories.

Silent Parts of Brain.—As a matter of fact, one cannot hope for definitely localizing symptoms from tumors in all parts of the brain. As Seguin pointed out, no matter what influence is exerted on certain parts of the brain, no symptomatic response seems to occur. These are the so-called silent parts. Only very limited parts of the brain give special symptoms, because of increase of pressure in their neighborhood and it is only when tumors occur in these parts that one can reasonably hope to trace their localization by means of the symptoms produced.

Recent Work on Tumors.—Dr. Max Schlapp said that recent nervous pathology contains some important and suggestive material for the diagnosis of brain tumors. It is now recognized that they are not as distinctly separated from each other in their course to the brain as has been thought, and that there are series of sensory nerve-fibers which come down from the brain and whose disturbance may easily occur as the result of brain tumor. The disturbances of sensation thus caused are somewhat difficult of detection, but their pathological basis has been traced by the Marchi method and this may lead to the discovery of symptoms that will help us in tumor localization.

Splenic Myelogenous Leucemia.—Dr. A. Sturmdorf read a paper on splenic myelogenous leucemia complicated by pulmonary, laryngeal and faucial tuberculosis. He also presented the patient and microscopical specimens of the blood changes. When the child came for treatment, she was suffering from night-sweats and had lost twelve pounds in weight. A sister who suffered from tuberculosis had recovered, but another had died from the disease. The patient was phthisical and had panniculus adiposus. There were eczematous patches on the elbows and knees.

Blood-Count.—The proportion of white blood-cells to red cells was one to eighteen. The number of white cells to the cubic millimeter was 150,000. Paroxysms of fever occurred occasionally and at these times the number of myelocites was increased while the number of polynuclear leucocytes was decreased. There seemed to be a distinct connection between these changes in the blood and the febrile course of the disease.

Treatment.—Potassium iodide was given in considerable doses and arsenic was employed for its alterative, tonic effect. The patient's paroxysms of fever became more and more rare, as she began to gain in weight. Even when the variations in the temperature were not very marked, however, distinct changes could be noted in the differential blood-count. Specimens for blood-examination were always taken at least four hours after a meal, in order to avoid any influence that digestion leucocytosis might have in producing changes in the number and relative proportions of white cells present. There were a number of megaloblasts found among the red blood-cells, but the other changes in the red cells were no more than would be found in a case of anemia corresponding in severity to the reduction of red blood-cells found in this case. There seems every reason to think now that the improvement in the patient's condition will continue and that the case has taken on a hopeful aspect.

NEW JERSEY STATE MEDICAL SOCIETY.

THE one-hundred-and-thirty-fifth annual meeting of this Society, which is the oldest medical organization on the American continent, was neld at Deal Beach on June 25, 26 and 27, 1901. There was a large attendance of members, and among the visitors was a delegation from the New York State Medical Association, consisting of Drs. John A. Wyeth, J. A. Corning, F. H. Wiggin, and Wm. F. Leszynsky.

Tributes to the memory of the late Dr. William Pierson of Orange, who died while holding office as the President of the Society, were paid by Dr. T. W. Harvey and others.

Dr. J. D. McGill of Jersey City, First Vice-President, opened the scientific proceedings by delivering an Address in which he surveyed the duties and defined the qualifications requisite in a medico-legal expert.

Thereafter a number of reports were read. One, dealing with diseases that had prevailed in the State during the year, expressed regret at the neglect of vaccination which had grown out of the rarity of smallpox in recent years and the false feeling of security which had thereby been engendered. Another referred to the medical inspection of schools and a third recommended the adoption of measures for the establishment of a State sanatorium for tuberculosis. The necessity of securing legislation for the prevention of the abuse of public charities and for obtaining State aid for hospitals also received attention.

Addresses on the progress in surgery, diseases of the nose and throat, and bacteriology were delivered respectively by Dr. Charles Young of Newark, Dr. B. A. Waddington of Salem, Dr. D. H. Bergey of Philadelphia.

Features Practicable for Preventing the Spread of Tuberculosis.—Dr. Henry Mitchell of Asbury Park read this paper. He showed, by the quotation of statistics and otherwise, the good results that had been accomplished by the establishment of sanatoria and the adoption of improved sanitary and hygienic methods; but said that a much more systematic campaign must be engaged in if physicians were to succeed in stamping out this most deadly of all diseases.

Arteriosclerosis and the Nervous System.—This was the subject of a paper by Dr. C. L. Allen of Trenton. The disease was usually associated with old age, but contributory causes were to be found in heredity, syphilis and the abuse of alcohol. The direct cause was the want of a sufficient blood supply, and the treatment called for was attention to the general health, hygiene and the free use of potassium iodide. In the course of the discussion which ensued one of the speakers advocated a return to the use of natural foods, chiefly nuts and fruit, and the avoidance of overeating.

The subject of Infant Feeding with special reference to the difficulties that were encountered in the management of infants deprived of natural milk was discussed in a paper by Dr. Alex. McAllister of Camden.

Some Observations on Suprarenal as a Hemostatic.—This was contributed by Dr. Norton L. Wilson of Elizabeth and gave the results of his own experiences and quoted those of others in the use of the active principle of the suprarenal gland in the treatment of nose, throat, eye and ear diseases.

Dr. Walter B. Johnson of Paterson said that adrenalin was a great improvement over the suprarenal gland, inasmuch as it was clean and not so difficult to keep as the mother substance.

Neuralgia and Allied Affections.—Dr. Wm. M. Leszynsky of New York showed how important it was to discover the origin of the disease in each case and treat it. It was desirable to begin with local rather than constitutional treatment, though judicious management of the general health was always advisable.

Plea for the Physician on the Witness Stand.—Dr. Daniel Strock of Camden pointed out that in New Jersey and other States, where no special enactment had been passed to modify the old common law which had been introduced from England, physicians who were called as witnesses were completely at the mercy of the cross-examining lawyer, who could force them to reveal private communications made to them by their patients. After discussion the matter was referred to the Committee on Legislation, with instructions to adopt measures to secure the passing of a law to ensure the reasonable protection of physicians who were called upon to testify in matters involving professional etiquette.

Modern Treatment of Gonorrhea.—This paper was read by Dr. Daniel Currie of Englewood and discussed by Dr. E. B. Silvers of Rahway, Dr. Mortimer Lampson of Jersey City, and others, all the speakers insisting, because of the complications that were apt to arise from it, that the disease should receive more serious and intelligent attention than it frequently did at the hands of general practitioners.

Treatment of Neurasthenia.—Dr. W. B. Stewart of Atlantic City read this paper. In making the diagnosis, care must be taken to eliminate hysteria and insanity, and then it became incumbent on the physician to ascertain the cause of the affection with a view to its possible removal and, in any case, as a guide to treatment. The paper was discussed by Dr. Philip Marvel of Atlantic City and Dr. G. H. Balleray of Paterson, the latter of whom remarked that there was no class of cases in which prophylactic treatment was of greater importance.

Dr. Samuel E. Armstrong of Rutherford, in a paper on "Some of the Infections, Their Genesis, Habitat, Consequences and Prevention," spoke particularly of abscess, syphilis and malaria. In connection with the latter he urged the adoption of concerted measures for the extermination of mosquitoes in New Jersey.

Milk as a Means of Contagion.—This was the subject discussed by Dr. R. C. Newton of Montclair and Dr. H. L. Coit of Newark, who did not agree as to the conclusions to be drawn from an outbreak of diphtheria which was alleged to be due to the milk-supply in the former place.

Intestinal Perforation in Typhoid Fever.—Dr. Joseph Stokes of Moorestown called attention to the importance of early diagnosis with a view to surgical interference.

Dr. Emery Marvel of Atlantic City read a paper showing the advantages to be derived from using ethyl bromide as a primary anesthetic to ether or chloroform.

Dr. Balleray of Paterson read a paper on "The Diagnosis and Treatment of Early Ectopic Pregnancy" and reported a case of Cæsarian section for deformity of the uterovaginal canal.

Cases of tumor of the neck and suppurative choroiditis were reported on, respectively, by Dr. J. C. McCoy of Paterson and Dr. Talbot R. Chambers of Jersey City.

The importance of the X-ray for diagnostic and medico-legal purposes was the subject of contributions by Dr. C. L. Leonard of Philadelphia and Dr. Carl Beck of New York.

Office-bearers for the ensuing year were chosen as follows: President, Dr. J. D. McGill, Jersey City; Vice-Presidents; Dr. E. L. D. Godfrey, Camden; Dr. H. Mitchell, Asbury Park, and Dr. A. W. Taylor, Beverley; Secretaries, Dr. E. W. Hedges, Plainfield, and Dr. Wm. J. Chandler, South Orange; Treasurer, Dr. Archibald Mercer, Newark.

It was announced that the Society is prepared to award a prize of $100 for the best essay on any subject connected with the practice of medicine or surgery, showing original thought or research or adding to the information of the profession.

It was decided to hold the next annual meeting at Atlantic City.

BOOK REVIEWS.

A REFERENCE HANDBOOK OF THE MEDICAL SCIENCES. Edited by ALBERT H. BUCK, M.D., of New York. Vol. II. Bla-Chl. Quarto; 838 pages. William Wood and Company, New York.

We expressed ourselves as highly pleased with the first volume of this important work. It was of the greatest value and was a credit to its authors, editor and publisher. This second volume is even better than the first in that it contains certain subjects which are of the greatest importance and which are treated in a highly satisfactory manner by acknowledged masters in their respective lines.

The subject of the blood in its normal and pathological aspects is exceptionally well treated. The lengthy and carefully detailed account of the methods of blood examination in particular are practical and will be of great service to any physician who is away from laboratories.

The article on brain, both macroscopically and microscopically, is monographic in its completeness and is perhaps one of the best accounts of this organ we have seen, apart from special works devoted to the subject. In the anatomical portions Wilder rides rough-shod over the ground and leaves the descriptive field a perfect mass of his idosyncratic etymological phrases which makes it impossible for any student not trained in Cornell to understand what is being said. It is to be regretted that so many minute contraversial points have been allowed to blemish what otherwise might have been a more valuable contribution. The article on the histology is exceptionally valuable and well illustrated.

Some of the articles on materia medica have not received the attention that they deserve in that the terminology is hopelessly antiquated and the analysis of the physiological action much behind the times. The vegetable drugs are among those which are best treated and have been more up to recent work. Take it from all points of view this is a praiseworthy volume in a desirable series.

BOOKS RECEIVED.

The MEDICAL NEWS *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* MEDICAL NEWS *will shortly appear.*

SPECIAL ARTICLES.

THE PRESIDENT'S CASE.

THE sad crime that laid our President low and for a time seemed to threaten his life has occupied so much attention that we have felt that the medical profession of the country would be interested in knowing the details of the President's injury and the subsequent course of the case, not from the more or less distorted statements of the secular press, but to as great an extent as might be under the circumstances from the members of the profession who have been in actual touch with the case. The following notes are from a special correspondent sent to Buffalo to consult the surgeons in charge and as far as possible obtain information at first hand:

The Wounds.—The President's case is a striking example of how little pain may be inflicted by bullet wounds and how little conscious of their infliction the wounded person may be. The wounds were received from a distance of less than three feet. The first shot penetrated the abdomen, wounding only soft tissues, and the President seems not to have felt it at all and not to have realized what had happened. This first shot, after penetrating the anterior abdominal wall, seems to have followed a course somewhat downward and outward. The President's assailant was carrying his right arm across his chest as if it were in a sling and as he straightened it to fire the general direction of the arm was downward. This circumstance perhaps accounts for the fact that the diaphragm was not wounded, although the wound of entrance of the bullet was about two inches to the left of the umbilicus and about on a level with it (standing position).

After the first shot the revolver, as is usual with weapons of this form, kicked upward so that the second bullet hit the sternum toward its left edge and near the articulation with the fourth rib. This bullet did not even penetrate the skin, but made only a discolored, bluish, bruised mark and was found later in the Presidents clothing. This bullet did not hit a button or other hard substance in its passage through the waistcoat and shirt, but fortunately seems to have been one of those weak-charge cartridges that sometimes are found among ordinary commercial revolver ammunition. The revolver used was of 32 calibre, of the variety known as bulldog, *i.e.*, with very short barrel, which favored the concealment of the weapon when carried in the hand.

There are different accounts as to how the President acted after the second shot. Practically all bystanders agree in saying that he was very little disturbed for a few moments while he stood facing the would-be assassin. Then a look of anxious surprise came into his face and, as those near grappled with his assailant, Mr. McKinley turned somewhat pale to those beside him. The shock and pain of his wounds had thus far been so little that he had to ask those around him if he were shot. When assured that he was, one of his first thoughts seems to have been for Mrs. McKinley, and he asked a secret-service man near him whom he know very well to see that the news be broken gently to her.

After a few moments the sight of blood and the excitement affected him, and he became weak and had to be supported. He reclined on a chair for a few moments until the Exposition ambulance could be summoned by telephone.

The Emergency Hospital.—Within ten minutes after the President was shot he was in one of the ambulances provided for emergency cases and was on his way to the Emergency Hospital on the Exposition grounds near the West Amherst gate. The director of the Pan-American Exposition Medical Department is Dr. Roswell Park. He had remarked more than once to the staff of the little hospital on the grounds that, while their small operating-room was unsuited for major operations and might never be needed for so serious a purpose, circumstances might arise in which it would be necessary to do important surgical work. There was no anticipation then of how grave and weighty an occasion would arise to test the perfection of the operating arrangements. The little operating-room, about 12 by 20, was to be the scene of the most important operation of recent years. Though small, it is reasonably well lighted and is thoroughly business-like in its air of absolute simplicity and cleanliness. How thoroughly aseptic everything about the little room was can be best judged from the post-operative course of the President's case. Great credit it would seem, now that the apportioning of commendation is in order, is due to the house staff, Drs. Hall and Zittel, and to the head nurse, Miss Walters, for the perfect condition that fortunately had been maintained.

As soon as the President arrived he was put on the operating-table, but without removing the stretcher on which he had originally been carried to the ambulance. This stretcher remained under him until after the operation was completed and served for his retransfer to the ambulance when he was moved to the home of Mr. Milburn. Dr. Roswell Park, the medical director, was at once summoned, but it was found that he was out of the city, operating at Niagara Falls. From there he came later by special train, arriving before the end of the operation. Considerable difficulty was experienced in finding Dr.

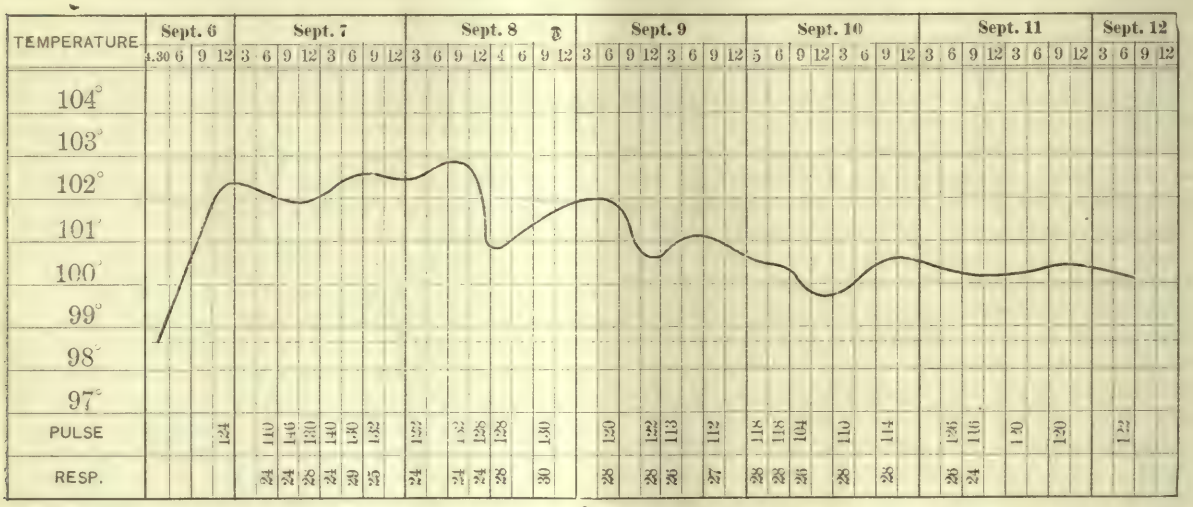
Mann. He was in a barber's chair when the urgent summons finally reached him, and left the shop, he said, with his hair only half cut.

The Operation.—As soon as it was found that Dr. Roswell Park could not come at once, Dr. Matthew D. Mann was summoned by President Milburn of the Exposition. He arrived at the hospital at five minutes after five. The President had been wounded at 4:07 p. m., so that practically an hour had elapsed. Very naturally this hour of waiting seemed very long for the President. Nothing was being done nor was there the slightest inkling of what would be done. The only sign of impatience manifested by the patient came at this time. He asked if others did not find the wait intolerably long.

All delay was over as soon as Dr. Mann arrived. Examination showed that, while the wound in the thoracic wall was only a superficial bruise, that in the abdomen had penetrated the abdominal cavity. The President's condition was good; the fact that laparotomy was of vital necessity and that every moment of delay while waiting for surer indications for surgical intervention would have been precious moments lost while infectious material was being absorbed. The stomach had been penetrated and some of the stomach contents were already extravasated into the abdominal cavity.

An opening was found in the anterior wall of the stomach in the neighborhood of the greater curvature. This opening was in the upper half segment of the stomach. Its position, small size and sharp inverted edges, and the contraction of that viscus served to keep it tightly closed. That on the posterior wall was larger and more irregular, but its edges were also inverted and the amount of leakage of gastric contents was not large. No bacteriological examination of this small amount of extravasated matter was made.

It was about three hours before his wound was received that the President had taken his lunch.



Temperature, Pulse and Respiration Record.

there was as yet no rise of temperature, the pulse was running slightly over 100 and the patient was evidently suffering slightly from shock. There had been two or more almost fainting spells and one-thirtieth of a grain of strychnine was given as a stimulant. A sixth of a grain of morphine was administered to quiet some restlessness due to the delay. The presence of a penetrating wound of the abdomen seemed to Dr. Mann sufficient indication for at least an exploratory laparotomy. As the events show, this was an extremely wise conclusion. Mr. McKinley at once accepted the doctor's opinion in the matter and expressed his entire willingness to submit to whatever treatment might be deemed necessary.

Nineteen minutes after his arrival, that is, at 5:24 p. m., Dr. Mann made his incision. The President had been given ether while the surgeons' personal preparations were making, and he took it very quietly and without excitement. The opening of the abdomen at once disclosed

It was fortunate that that meal was taken at Niagara Falls, where, according to tradition, at least lunches are not prone to be excessive in quantity. Though it was so long after lunch, the President's stomach was found about half full. The edges of the wound were repaired with Lembert sutures. The posterior wall of the stomach was then exposed by turning the organ upward and backward, avoiding any contact with the intestines, and a wound corresponding to that in the anterior wall was found. This was sutured as the other one. All extravasation was now at an end. No other visceral wounds could be found. There was practically no hemorrhage. The abdomen was thoroughly flushed out with sterile normal salt solution. As the bullet had not been found during the course of the rather lengthy manipulations (the patient was under ether about an hour and a half), further search for it was deemed inexpedient. The apparent direction of this bullet was, as has been said, away from the median line. There was no danger

that it had injured the body of a vertebra, as in Garfield's case, and the fact that there was no noticeable hemorrhage seemed to indicate that it had lodged in the muscles of the back, where it might well remain without doing any harm.

The question of using the Roentgen rays to locate the bullet is still open. Unless the ball gives rise to symptoms of irritation, however, the President will not be disturbed and the use of the Roentgen rays will be postponed until he is well on the road to convalescence. So far there has not been the slighest indication that the bullet is causing any trouble, and the indications are entirely for expectant treatment.

We here append the temperature chart prepared from the special bulletins of the case. It is to be noted that the temperature was taken by the rectum until Tuesday morning. This makes the earlier readings a trifle over ½° F. higher than they would have been if taken by the mouth.

A Cutaneous Abscess.—There was a thrill of apprehension on Wednesday morning at the announcement that a second operation had been performed on the President late Tuesday night. This was not an operation, but only a dressing of the incision. For forty-eight hours before the President had been complaining of some tenderness in the neighborhood of the wound and this had not only persisted, but increased. It was thought better to investigate the cause for this discomfort. A small superficial collection of pus along the edge of the wound was found to be forming. It was noticed by Dr. Mann, who called the attention of the assistant surgeons to it while making his incision, that a small portion of clothing had been carried into the abdominal wound. It did not reach the abdominal cavity, but was found near the bottom of the fatty layer of the abdominal wall. The shreds of clothing were removed as carefully as possible, but it is a well-known experience that portions of such material are liable to be left in the wound. This Dr. Mann considers to have been the origin of the superficial suppuration that was found to exist. The collection of pus was evacuated without in any way disturbing the coaptation of the wound edges and the wound was redressed as before. As a result of the relief thus afforded the President passed a more comfortable night on Tuesday and was in excellent spirits on Wednesday, asking for the paper and wanting to talk more than the attending surgeons considered good for him. Feeding by the mouth was begun on Tuesday morning and was well borne. Since Wednesday all nourishment has been given in this way, and the rectal alimentation of the first few days, which was fortunately always satisfactorily retained and absorbed, has been discontinued.

The Outlook.—As we go to press all the surgeons in attendance are agreed that danger of peritonitis is over. There is, however, still some danger of sepsis. Wounds in civil life differ from those in military life in the greater after-danger of septic involvement. Revolver cartridges are more liable than are rifle cartridges to have been handled frequently, to have been carried in dirty pockets, and to have come in contact with various forms of infectious materials that may prove of serious consequence when buried in the tissues. Moreover, revolver cartridges are covered with a coating of grease and this encourages an accumulation of manifold microbic material some of which may prove to be of virulently infectious nature. Rifle bullets are practically always sterilized by the intense heat developed by the powder at the moment of their discharge. Their rapid progress through the air while in a heated condition still further serves to cleanse them of any extraneous material that may chance to have accumulated on their surfaces. This cleansing process is very effectually begun by the rifling of the rifle barrel through which the bullet forces its way. All of these favorable factors are lacking in the case of the revolver bullet, and so it is possible that in any given case such a bullet may carry infectious material with it into the tissues. If this were in small amount Nature might effectually wall it off and no serious consequences result. On the other hand, such infectious material might lie seemingly dormant for days, but really slowly gathering strength by multiplication, and when its toxins were elaborated in sufficient amount they might paralyze protective chemotaxis and produce a septic condition.

Blood-counts made by Dr. Eugene Wasdin demonstrated the absence of leucocytosis. The differential count of leucocytes showed no departure from normal and the usual number of red cells was present. Thus the evidence derived from the blood-counts indicates the absence of any sepsis.

There is nothing in the President's condition at the present moment to hint at such an unfavorable possibility. He is recovering rapidly from his wound without a single disturbing symptom. He has not had any peritonitis and the danger from that is past. The disturbance of pulse and temperature noted for forty-eight hours after the operation and that were a source of no little disquiet to those who did not realize all the conditions were due to three principal factors, (1) the shock of the wound itself, (2) the shock due to the manipulation of the stomach and intestines during the operation, and (3) the disturbance of the nervous system and the shock incident to the intra-abdominal manipulations, all having been necessarily done in close proximity to the solar plexus. Dr. Mann refers most of the immediately subsequent disquiet to solar plexus irritation. This is now a thing of the past and every sign points to assured speedy and complete recovery. If the President were younger by twenty years it would be possible for him to be up and around in ten days. As it is his reaction all through the course of the affection has been that of a man much younger than his years. There is, then, really very little danger of sepsis developing and its possibility is held out by the surgeons merely in order not to seem too sure of the distinguished

patient's recovery, for, after all, stranger things have happened than a turn for the worse in cases that have apparently progressed as favorably as this.

Older surgeons would still fear from the secondary manifestations of wounds. For the military surgeons of a quarter of a century ago there would still be (at least for nine days after a bullet wound) some danger from secondary hemorrhage, for instance. As is well understood now these so-called secondary complications were really due to gradually developing septic conditions. As to secondary hemorrhage, there having been no primary hemorrhage, the danger in this respect seems more or less imaginary. The fact that the attending surgeons look to the possible development of sepsis as the only complication to be feared now shows that we have not departed as far as might seem from the point of view of older surgeons.

The possibility of such a retained bullet finding lodgment beside an artery and by pressure absorption opening the vessel and causing hemorrhage was formerly seriously entertained by the surgeons of a generation ago. It is now generally conceded that it was never the mechanical factor of pressure alone that worked harm in such cases; there was always the accessory element of septic material present on the bullet and producing preliminary tissue changes. The dangers to be feared, then, are all concentred in the word sepsis, and for those who fear to tempt fate by too good a prognosis this is the rational method of giving hostages to fortune.

Besides the question of sepsis there remains, of course, the doubt whether the bullet may not have found its way after its course in the abdomen through the diaphragm and so be lodged in the pleural cavity. This is, as is well known, a very frequent lodgment for bullets that penetrate the stomach. The possibility of this was a great source of uneasiness to the attending physicians for the first two or three days. But there has never been any, even the slightest, interference with respiration. There has been no pain nor diaphragmatic discomfort, and now the question of the pleural cavity as the resting-place of the bullet is dismissed from all minds. As said when describing the wounds, the weapon seems to have been directed somewhat downward when the first shot was fired and this fortunate circumstance spared subsequent pleural complications and the serious sequelæ that would be almost sure to have followed sooner or later.

The Prisoner.—Owing to all that has been said in sensational journals about the prisoner as a typical criminal he comes into the medical aspects of the case. It will be hard for the criminologists to bring him under any of their classifications of innate criminality. He has a young foreign-looking face that even now, with its week's growth of beard topped by unkempt hair, is not unpleasant. He has none of the irregular features so often suggested as typical of the born criminal. There are no hints of supraciliary ridges. His eyes are normally set and of normal size. His ears do not project more than normally and they are equal in size and set at the same level. The jaw is a little heavy, but there is a suggestion of weakness about the lips. Those in immediate custody of him in Buffalo consider him a rather ordinary-looking young foreigner, without any of the facial traits they are so accustomed to see in habitual criminals or those imprisoned for violence.

THE GARFIELD CASE: A SUMMARY OF ITS IMPORTANT FEATURES.

ON THE second of July, 1881, President James A. Garfield was shot from a distance of six feet with a large 42-caliber revolver. Two shots were fired, one passing through his coat sleeve, the second penetrating the back and causing the President to fall to the ground from the shock. He was at first taken to the second story of the Baltimore station, in which building the shooting occurred, and examined by Dr. D. Willard Bliss of Washington.

The point of entrance of the bullet, which was oval and sharply pointed, was on the right side, in the tenth intercostal space, four inches from the mid-spinal line and on a line with the eleventh rib. A slight bloody discharge oozed from the wound. A Nelaton probe was passed into the wound and, passing downward and forward for a distance of three and one-half inches, seemed to engage in a pocket, or cavity. No foreign body was detected in this cavity. On withdrawing the probe it became evident that a rib had been fractured, as the broken ends caught and held the probe, which could only be disengaged after pressure on the sternal end of the ribs. The wound was large enough to admit the little finger, but Dr. Bliss was able to feel only as far as the lower border of the rib, where his finger came in contact with a firm blood-clot. Further probing failed to find the bullet, and it was deemed advisable to desist, since it was feared that the internal viscera were injured, particularly the liver, and that fatal hemorrhage might result.

By this time Drs. Townshend, Purvis, Reyburn, Norris, Lincoln and J. B. Hamilton reached the patient's bedside, but inasmuch as severe collapse and nausea were present it was decided that no further explorations be made; temporary dressings were applied and after a short interval President Garfield was removed to the White House.

On his arrival the pulse was very feeble and rapid and of very low tension; the respirations were slow and sighing in character and the body surface was very cold. Vomiting had been free and persistent, the body was covered with profuse perspiration, the voice was husky and there were severe pains in the limbs. The patient was placed on the right side in order to facilitate drainage, water was necessary to relieve the great thirst and one-eighth of a grain of mor-

phine was administered to control the pain and to aid if possible in reaction.

The accident happened at nine-thirty in the evening and by ten the following morning the condition was as just given. One-sixth of a grain of morphine had to be given at eleven in order to relieve the excessive pain. The pulse responded very feebly to the stimulation; nausea and vomiting continued until seven in the evening of the 3d at half-hour intervals.

The clothing was not removed until 5.30 p. m. when, so great was the shock, it was decided to cut away his garments in order to minimize movement. The first examination showed a well-defined area of dulness over the entire wound surface, which was then supposed to be due to a hemorrhage from the liver and later in the evening, at 7, it was decided that, as far as could be told from the very indefinite symptoms, there was internal hemorrhage and a very unfavorable prognosis was given. At ten the pulse was 158, temperature 96.5° F., respiration 35. At eleven-twenty a reaction occurred, the pulse dropped to 120 and the temperature and respiration became normal. A fitful sleep ensued and during the morning of July 4th he was feeling fairly comfortable; slight nausea and regurgitation were the only symptoms of note. All during this time the mental processes were not affected. He was perfectly rational and attended to a few business and family details without inconvenience. He was particularly anxious to know his own condition.

The wound itself gave no marked discomfort. There was much oozing of dark venous blood. On the removal of the dressing a consultation was held by Drs. Bliss, Wales, Barnes, Woodward, Lincoln and Reyburn. The pulse was then 115, temperature and respiration normal. The patient was cheerful and small amounts of morphine controlled the pain in the extremities. The intestinal and bladder functions were normal. There was some slight tympanites, but no further evidences of any peritonitis. Dr. D. Hayes Agnew of Philadelphia and Dr. Frank H. Hamilton of New York were then called in consultation.

A careful and complete examination was made by each surgeon, although no operative features were undertaken. Their diagnosis was based on the following data: The angle of incidence of the ball, taking into account the relative positions of the two at the time of the shooting; the direction of the ball through the tissues, as far as the probing had been able to determine that; the severe pains and hyperesthesia of the limbs, especially of the right side, with their gradual variation; the repeated fruitless trials to pass the probe or other suitable exploratory instrument more than half an inch in any direction beyond the fractured rib except slightly forward and anterior to the twelfth rib where the probe penetrated two inches.

These facts, combined with the manifest symptoms of profound shock and the long period of collapse, all seemed to point to extensive injury of the abdominal viscera. The increased pain and hyperesthesia of the right side pointed to injury of the nerve-trunks. Injury to the spinal cord itself was excluded.

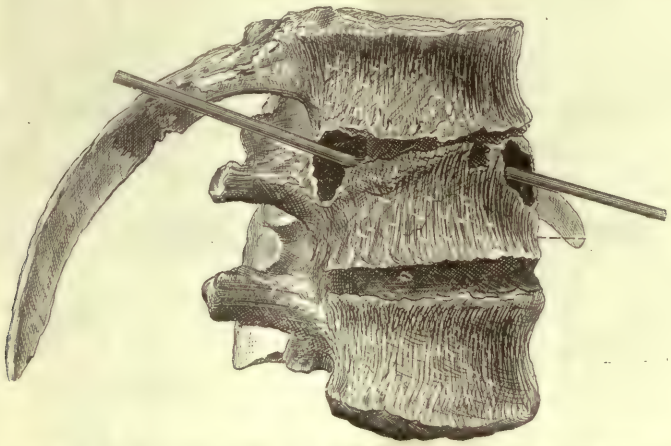


FIG. 1. Shows the course of the ball through the first lumbar vertebra, its direction being indicated by the probe.

The possible course of the bullet was thought to be in one of three directions; either it had gone into and through the liver, or backward at a right angle so that it involved the spinal column, or, finally, it might have gone forward into the abdominal cavity behind the peritoneum. The first supposition, that the liver had been perforated, was excluded by Drs. Agnew and Hamilton. The second diagnosis did not seem probable, and it was deemed that the most reasonable diagnosis was that of the third alternative, although its possibility rather than its probability was upheld by Dr. Agnew.

The early progress of the case was very favorable; so much so that it was decided not to perform any radical operation, such as cutting away a portion of the fractured rib in order to trace more accurately the probable course of the bullet.

By July 4th, the pain, hyperesthesiæ and vom-

iting had almost disappeared, but there was still marked soreness of the feet. During the month of July the case progressed very favorably. There were slight fluctuations; thus, from the 3d to the 6th the variation of the pulse had been from 98 to 126; the temperature had risen to 102° F., and the respiration had varied from 19 to 24. On Friday of the following week, six days after the shooting, some pus had made its way to the surface of the wound, and the highest temperature of the early stages was recorded on the tenth day, it being then 102.8° F. The official bulletins at that time said that it was thought that the bullet was in the abdominal cavity, from which it was hoped it could be removed. On the 13th it was officially reported that circumscribed peritonitis had developed, although a mild amount of peritoneal inflammation had been apparent from the early stages. Notwithstanding this the President's condition remained fairly satisfactory until the evening of July 23d, when a severe chill occurred at seven o'clock. Two days before this a pus sac had shown itself below the twelfth rib in the neighborhood of the erector spinæ and beneath the latissimus dorsi. It was evacuated, but the aggravated symptoms seemed to have been caused by a deeper process and a free incision was made into the pus sac, which was found to communicate with the fractured rib, a portion of which was removed. Recovery not being prompt, three days later this wound was enlarged and a portion of the eleventh rib was exsected. At this time upward and backward pressure on the abdominal wall caused a welling up of a peculiar whitish and firm pus, the larger opening facilitated its removal and the symptoms abated until August 6th, when a slight exacerbation of temperature was manifested.

It was apparent that the pus had made for itself a new canal and had burrowed down behind the peritoneum and lodged in the right iliac fossa. It was also supposed that the bullet had followed this same course and that the pus sinus and bullet track would be found to be the same.

On August 8th the patient was anesthetized, ether being employed, and the pus canal was opened by an incision which was carried downward and forward through the oblique muscles. On careful dissection a deeper burrowing sinus was discovered, and the incision was carried through the transversalis muscle and fascia. The results seemed to promise well for a week, although there was persistent nausea and vomiting which necessitated the continuance of rectal feeding.

It was interesting by way of comparison to note the efforts made on this and on other occasions to locate the bullet by means of Bell's bullet-finder or induction balance. On August 1st the report of Drs. Bell and Taintor was as follows: "Under the supervision of the attending surgeons, Professors Bell and Taintor this morning made another application of the electrical apparatus known as the induction balance, with a view to completing the tests of last week, which were not entirely conclusive, and ascertaining

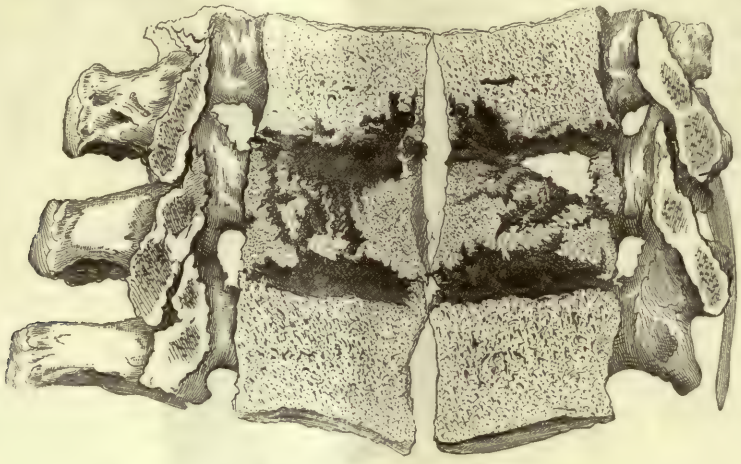

Fig. 2. Shows the above specimen sawn open.

definitely and certainly if possible the location of the ball. * * * They tried this improved apparatus on the President's body for the first time last week, and although it indicated faintly the location of the ball, it was afterward found to be slightly out of adjustment, and the experiment was not regarded as perfectly conclusive. The results of this morning's tests, however, are entirely satisfactory both to Professors Bell and Taintor and to the attending surgeons, and it is now unanimously agreed that the location of the ball has been ascertained with reasonable certainty, and that it lies, as heretofore stated, in the front wall of the abdomen, immediately over the groin, about five inches below and to the right of the navel." The report of the autopsy negatived these findings.

Ten days after the operation a slight parotitis appeared, this finally suppurated, involving the right facial nerve with attending facial paralysis. This local abscess soon healed and with it the mental and gastric symptoms improved, but dur-

ing the latter part of August a number of superficial acneiform pustular eruptions developed, at first in the arm-pits and later on the exposed surface of the body, indicating the much depressed vitality of the tissues. These were opened and healed rapidly. On August 26th there was a discharge of pus through the mouth and from the auditory canal. During this period there was considerable mental disturbance, although it was possible to bring him to a perfectly rational state by fixing his attention. The inflammation of the mouth extended to the trachea, larynx and bronchi, with the development of an acute bronchitis, but these symptoms ameliorated when the parotid suppuration began to discharge. On September 6th the President sank and died twenty-five minutes later.

On the following day a necropsy was performed by Dr. D. S. Lamb, assisted by Dr. J. J. Woodward. The results of the finding applicable to the wound showed the following: "Behind the right kidney, after the removal of that organ from the body, the dilated track of the bullet was dissected into. It was found that from the point at which it had fractured the right eleventh rib (three and one-half inches from the vertebral spine) the missile had gone to the left obliquely forward, passing through the body of the first lumbar vertebra and lodging in the adipose connective tissue immediately below the lower border of the pancreas, about two and one-half inches to the left of the spinal

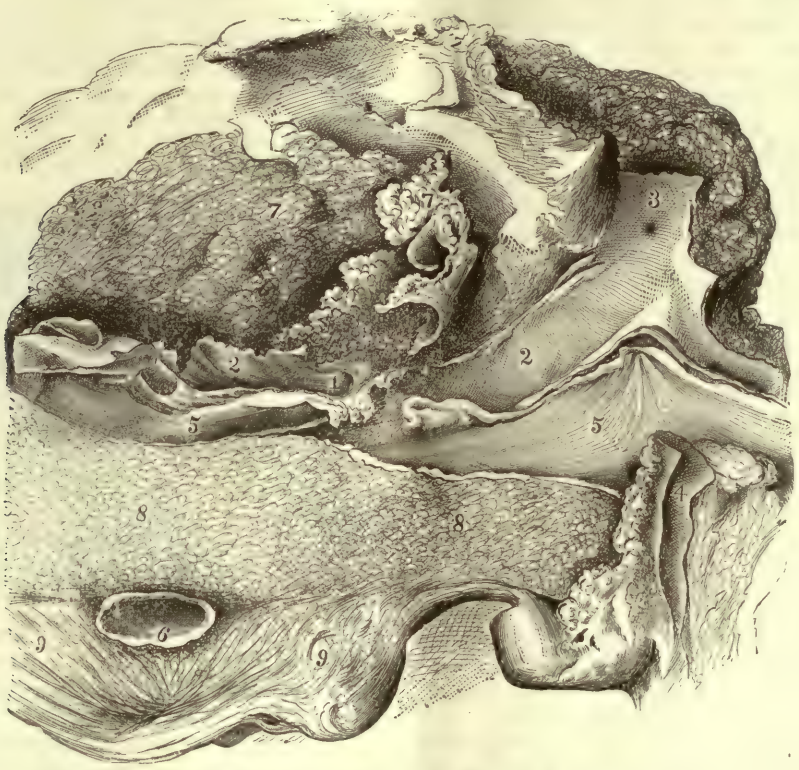

FIG. 3. Shows (1) the point at which the splenic artery gave way; (2) the splenic artery; (3) the coeliac axis; (4) the superior mesenteric artery; (5,5) the splenic vein; (6) the cyst in which the ball was found; (7,7) a portion of the mass of extravasated blood; (8,8) the pancreas; (9,9) adipose tissue behind the transverse meso-colon.

was removed to Elberon, New Jersey, in order that the invigorating air of the seashore might restore his tone and aid in recovery. He stood the journey remarkably well and progressed very favorably until the evening of the 15th, when the temperature rose after a sharp chill and the pulse to 120. With the chill violent and excruciating pains of the chest came on, to be relieved only for a time and then to recur in the paroxysms-like attacks of angina pectoris. These were due to dissecting hemorrhages. On the 18th another chill occurred, with a rise of temperature. The following morning the pulse was very rapid and feeble, the temperature 108° F., and consciousness impaired. At ten-ten in the evening unconsciousness came on and the column and behind the peritoneum. It had become completely encysted.

"The track of the bullet between the point at which it had entered the first lumbar vertebra was considerably dilated and the pus had burrowed downward through the adipose tissue behind the right kidney and thence found its way between the peritoneum and the right iliac fascia, making a descending channel which extended almost to the groin. The adipose tissue behind the kidney, in the vicinity of this descending channel, was much thickened and congested by inflammation. In the channel, which was found almost free from pus, lay the flexible catheter introduced into the wound at the commencement of the autopsy; its extremity was found doubled

upon itself, immediately beneath the peritoneum, reposing upon the iliac fascia, where the channel was dilated into a pouch of considerable size. This long, descending channel, now clearly seen to have been caused by the burrowing of pus from the wound, was supposed during life to have been the course of the bullet.

"The twelfth dorsal, together with the first and second lumbar vertebræ and the twelfth rib were then removed from the body for more thorough examination.

"When this examination was made, it was found that the bullet had penetrated the first lumbar vertebra in the upper part of the right side of its body. The aperture by which it entered involved the intervening cartilage next above and was situated just below and anterior to the intervertebral cartilage next above and was situated just below and anterior to the intervertebral foramen, from which its upper margin was about one-fourth of an inch distant. Passing obliquely to the left and forward through the upper part of the body of the first lumbar vertebra, the bullet emerged * * * and involved the intervertebral cartilage just above. * * * Both the first and second lumbar vertebræ were partly destroyed by ulceration. * * * The spinal cord was not involved. * * * Beyond the first lumbar vertebra the bullet continued to go to the left, passing behind the pancreas to its final resting-place. Here it was enveloped in a firm cyst of connective tissue which contained, besides the ball, a minute quantity of inspissated, somewhat cheesy pus, which formed a thin layer over a portion of the surface of the lead. * * * For about an inch from this cyst the track of the ball behind the pancreas was completely obliterated by the healing processes. Thence as far backward as the body of the first lumbar vertebra, the track was filled with coagulated blood, which extended on the left into an irregular space rent in the adipose tissue behind the peritoneum and above the pancreas. The blood had worked its way behind the spleen into the abdominal cavity. * * * It was found that the fatal hemorrhage proceeded from a rent nearly $^4/_{10}$ of an inch long in the main trunk of the splenic artery, two and one-half inches to the left of the cœlic axis. This rent must have occurred several days before death. * * * The surgeons assisting at the autopsy were unanimously of the opinion that on reviewing the history of the case in connection with the autopsy, it is quite evident that the different suppurating surfaces and especially the fractured, spongy tissue of the vertebra, furnish a sufficient explanation of the septic conditions which existed during life."

This report was signed by Drs. D. W. Bliss, J. K. Barnes, J. J. Woodward, Robert Reyburn and D. S. Lamb.

The names of Drs. Agnew and Hamilton were not appended to this report although they attended the autopsy and concurred in all the statements made.

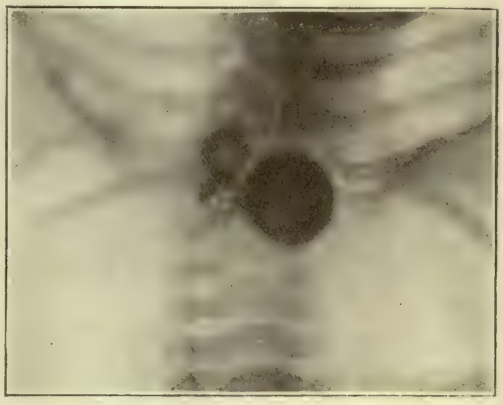
ORIGINAL ARTICLES.

A CASE OF FOREIGN BODY IN THE ESOPHAGUS.[1]

BY RUSSELL S. FOWLER, M.D.,
OF NEW YORK;
ADJUNCT TO THE SURGEON-IN-CHIEF TO THE BROOKLYN HOSPITAL; ASSISTANT SURGEON TO THE METHODIST-EPISCOPAL HOSPITAL, AND TO THE GERMAN HOSPITAL, BOROUGH OF BROOKLYN.

THIS patient was referred to me by Dr. Arthur C. Jacobson to whom I am also indebted for the medical history of the case.

Susan A., two years and two months old, enjoyed perfect health up to the evening of March 31, 1901. On this date her father, while playing with the child, carelessly allowed her to place a penny in her mouth, whence it quickly passed into the esophagus beyond his recovery. The parents expecting the coin to pass naturally, delayed taking their child to the family physician until April 4th. Then, worried by the persistence of the symptoms initiated by the swallowing of the penny, *i. e.*, inability to swallow solid food, the regurgitation of which was immediate, and



spasmodic attacks of coughing, they sought relief. No blood was coughed up, nor was there at any time any complaint of pain. Liquids could be swallowed quite easily.

No attempt was made to locate the coin at this time, but a soft diet was ordered for her in the hope that the penny would pass downward. The child was seen four days later, by which time she had become somewhat thin and pale. Swallowing had become quite easy, probably due to a change in the position of the penny. This change was so marked that the parents were disinclined to have anything further done.

At my suggestion, however, a Roentgen-ray picture was taken by Dr. Bender on April 10th. Chloroform was administered for the purpose of keeping the small patient quiet. This picture showed the penny hanging vertically in the esophagus at the level of the sternal notch. The plane surfaces were antero-posterior, forming a partition on either side of which food could pass. The transition from difficult to easy deglutition was

[1] Von Eiselsberg und Ludloff, Atlas klinisch-wichtiger Roentgen-Photo-gramme, Tafel I. und II.

undoubtedly due to the coin swinging from an oblique into a vertical position.

On April 15, the patient was admitted to the German Hospital where, with the kind assistance of Dr. Bender, I located the coin with the fluoroscope. The patient was anesthetized with chloroform, the head overhanging the edge of the table. Owing to the small size of the patient's esophagus a slender whalebone-handled coincatcher was selected, the whalebone stem terminating in a small silver swinging basket. Even this slender instrument was passed with difficulty though no force was necessary. The difficulty was chiefly due to the stiffness of the whalebone. With the fluoroscope the coincatcher could be seen as it passed beyond the coin; then as it was withdrawn the coin could be seen to fall into one side of the basket and be carried upward with it. As the pharynx was reached the patient's head was lowered and the coincatcher with its imprisoned penny withdrawn.

The subsequent history of the case was uneventful. The child was kept on fluid food for a few days and then resumed her usual diet. No bad after-effects of any kind occurred.

I have records of three somewhat similar cases in which a Roentgen picture was taken. In all three cases esophagotomy was finally resorted to after other efforts at dislodging the coin had failed. In one case the coin was not found by operation, but appeared later at stool.

So far as my own experience goes I should recommend complete anesthesia in children; the use of extremely flexible instruments, particularly in children; the lowering of the patient's head as the foreign body approaches the pharynx to avoid the possibility of its falling into the larynx; the constant visual supervision of the instrument through the fluoroscope; and, finally, that such instrumentation should always precede any operative attempt at removal.

INFANTILE ATROPHY.[1]

BY JOHN LOVETT MORSE, A.M., M.D.,
OF BOSTON;
INSTRUCTOR IN DISEASES OF CHILDREN, HARVARD MEDICAL SCHOOL; ASSISTANT VISITING PHYSICIAN AT THE CITY HOSPITAL AND AT THE INFANTS' HOSPITAL, BOSTON.

THE term infantile atrophy, and its synonyms, athrepsia and marasmus, should be applied only to those conditions of wasting which, in the light of our present knowledge, are primary and not secondary to other morbid processes. These cases of primary wasting form a small, but perfectly definite clinical group, easily distinguishable from the more common cases of wasting secondary to other diseases and conditions.

Definition.—Infantile atrophy is a morbid condition of infancy in which there is extreme wasting of the soft tissues of the body without demonstrable organic lesions. It is the expression of continuous, insufficient nutrition due probably to defective absorption or assimilation rather than to defective digestion.

Etiology.—It occurs most frequently during the first six months of life, less frequently during the second six, and is rare after the first year. It is more common in cities than in the country, and among the poor than among the well-to-do. It almost never occurs in breast-fed infants. Prematurity, inherent weakness of constitution, lack of warmth, light, pure air and cleanliness are most certainly predisposing factors. Unsuitable food undoubtedly favors its development. In a certain number of cases it follows, or is engrafted on, severe intestinal disturbances, whether functional or organic. None of these things, however, afford a satisfactory explanation as to the origin of the disease. They are all common, but atrophy is rare. They all give rise to other conditions as well as to atrophy. Therefore, some other factor, presumably common to all cases and more important than these, must be present. This factor has not yet been discovered. The wasting of the tissues, which is the chief symptom of the disease, must be due, in the absence of demonstrable lesions, to an insufficient supply of nutriment. As in typical cases the processes of digestion are apparently carried on normally the source of this insufficient supply of nutriment must be some disturbance of the functions of absorption or assimilation. The nature of this disturbance of function and the causes, except as imperfectly detailed here, are at present unknown, the examination of the urine and feces having thus far failed to furnish any information of importance as to the character of the disturbances of either absorption or metabolism.

Pathological Anatomy.—The pathological findings afford little or no information as to the nature of the disease. All the tissues are dry and the fat is almost entirely wanting in the skin and about the internal organs. There is extreme atrophy of all the muscles. The heart is, as a rule, normal but may be fatty. The liver is not infrequently enlarged, and fatty. The kidneys are sometimes fatty and often contain uric-acid infarctions. These fatty changes in the various organs are undoubtedly merely secondary manifestations of the impaired nutrition. There is marked atrophy of the mucous and submucous coats of the intestines. Microscopical examination, however, fails to show any characteristic lesions. The superficial lymph-nodes are, as a rule, enlarged. The retroperitoneal and mesenteric nodes may be, but if so, show no abnormal changes microscopically. The lungs often show areas of atalectasis or the lesions of complicating bronchitis or bronchopneumonia, while the intestines may show those of a complicating catarrhal or follicular inflammation.

Symptoms and Course.—The one prominent symption of infantile atrophy is failure to gain or loss of weight. This is the earliest and for a time may be the only symptom. It is constant and progressive. In the typical case there are no

[1] Read at the annual meeting of the Massachusetts Medical Society, June 11, 1901.

symptoms of disturbed digestion. The appetite is, as a rule, diminished but may be voracious. Thirst is increased. Vomiting is unusual. The stools are normal or constipated. The child is usually quiet and apathetic, but may be peevish and irritable. The temperature is normal or subnormal. Sooner or later complicating functional disturbances of digestion or inflammatory conditions of the gastro-enteric tract arise and add vomiting, diarrhea, colic and fever to the list of symptoms. These may be acute or chronic, temporary or lasting.

The picture of an advanced case of atrophy is very characteristic. The fontanelle is small and sunken. The bones of the skull overlap. The face is pinched, the chin pointed, the bones prominent and the skin wrinkled, especially about the mouth and forehead. A cry is distressing; a smile dreadful. The eyes are wide open and staring or half closed and dull. The cry is feeble and the movements slow and infrequent. The tongue is thickly coated or dry and red, while the mucous membrane of the mouth may show herpetic lesions or those of thrush. The skin, everywhere wrinkled, yellowish, dry and desquamating, hangs in folds from the bony prominences, as if draped over the skeleton. Pustules on the scalp and body and intertrigo about the genitalia and buttocks are common, while there is often an excessive growth of lanugo on the neck and back. Ecchymoses occur not infrequently. The abdomen is sunken and lax. The extremities are cold, the hands look like claws, and the muscles like strings. Rigidity of the extremities is not uncommon, presumably as the result of cerebral anemia. Edema sometimes occurs. Chronic otitis media is not infrequent.

Emaciation continues, the strength steadily fails, and finally the child becomes too feeble to suck. The action of the heart becomes weak and the circulation poor. The pulse is feeble and rapid, although sometimes slow. The extremities become cold and cyanotic and pulmonary atelectasis develops. The respiration is weak and superficial and the temperature subnormal. Death finally occurs after gradual, progressive failure. In some instances sinus thrombosis results from the feeble circulation and death may be preceded by spastic phenomena or convulsions. Functional and inflammatory disorders of the gastro-enteric tract are frequent and serious complications. Bronchitis and bronchopneumonia are not unusual complications, while an acute, general, bacterial infection often brings the disease to a sudden close.

The urine is usually diminished in amount and contains an excess of both urea and uric acid. It not infrequently contains albumin and sometimes sugar. The blood shows the conditions ordinarily found in secondary anemia. In some cases there is also a moderate increase in the number of white corpuscles.

Diagnosis.—The condition is to be differentiated from starvation, wasting secondary to functional or organic disease of the stomach or intestine, congenital syphilis and disseminated tuberculosis.

The differentiation from starvation due to congenital deformities is self-evident; that from starvation due to insufficient but suitable food is also plain. The rapid gain when sufficient food is given will settle any doubt. That from starvation due to food of improper character can usually be readily made by a careful consideration of the food in question and by the rapid improvement when a suitable food is given.

The differentiation from gastro-intestinal diseases associated with wasting must often be a difficult one, as infantile atrophy is frequently complicated by them. In them, however, the wasting is not the one prominent symptom, as it is in infantile atrophy. It is, moreover, not the earliest but a late symptom, always following other symptoms of gastric or intestinal disturbance. Vomiting and diarrhea are more common. The stools show evidences of indigestion and inflammation not present in those of infantile atrophy. The abdomen is, as a rule, distended. The temperature is usually elevated. There is fretfulness and sleeplessness instead of apathy. The course is not so progressively and uninterruptedly downward. Infantile atrophy in the vast majority of cases occurs in the first six months and rarely after the first year; the other conditions occur at any age.

The history of syphilis in the parents and the presence of other signs of syphilis, active or inactive, make the diagnosis from syphilis with emaciation easy.

The differentiation from disseminated tuberculosis, however, is frequently difficult and at times almost impossible, for in the tuberculosis of infancy the local symptoms are, as a rule, subordinate to the general. A family history of tuberculosis or of continued exposure is of certain but not of great importance. So also is a doubtful milk supply. The temperature is likely to be elevated in tuberculosis, but is not always. On the other hand, in some cases of infantile atrophy, especially if complicated, there is fever. Diarrhea cannot be considered as pointing especially to tuberculosis of the intestines, as it may as well be due to some complicating condition. Enlargement of the spleen is in favor of tuberculosis. Enlargement of the liver may occur in either. Râles are almost always present in the lungs of cases of atrophy as the result of congestion or edema or of a complicating bronchitis. Solidification of the lung is the most important point in the differential diagnosis, except in the rare instances in which tubercle bacilli can be demonstrated in the sputum or feces. Even solidification, however, may be due to a complicating bronchopneumonia.

Prognosis.—The prognosis is always grave. Most of the cases result fatally. If recovery takes place it is always slow and is usually interrupted by frequent relapses. When recovery takes place, however, it is complete and the

future development is not interfered with. Complicating functional or inflammatory disturbances of the gastro-enteric tract render the prognosis still more grave, as do diseases of the respiratory tract. Other diseases occurring in infants with atrophy carry a very bad prognosis. Secondary general bacterial infections always result fatally.

Treatment.—There is no known drug which has any specific action in infantile atrophy. As the condition is presumably due to some vice of absorption or assimilation the treatment must necessarily consist largely of regulation of the diet with the object of providing some food which can be easily absorbed and utilized by the individual infant. The same food will not fit every case. The best food and the one which is always to be tried first, if circumstances permit, is human breast milk. The best substitute for it is some modification of fresh cow's milk, prepared either at the laboratory or at home. Although there are no data based on scientific experiments to suggest in what way cow's milk should be best modified for these cases, clinical experience has shown that, as a rule, they do best on milks which contain a low percentage of fat, a moderate percentage of sugar and a moderate or somewhat high percentage of proteids. For some unknown reason they seem unable to utilize any but small amounts of fat and continue to lose if large quantities are given. Hence the treatment by large doses of cod-liver oil is not only useless but harmful. They do seem able, however, to make use of considerable amounts of proteids. The proportions which are best suited for the early treatment of the majority of these cases lie within the following limits:

Fat	0.50 to 1.00
Sugar	4.00 " 5.00
Proteids	1.00 " 2.00

Whey mixtures, furnishing, as they do, a considerable proportion of the proteids in the form of the more easily digestible and absorbable lactalbumin, are especially useful in giving these high percentages of proteids. Unfortunately, their preparation outside of the laboratory is decidedly difficult. A portion of the proteids may also be added to the milk mixtures in the form of egg-albumin, which is more easily absorbable than the milk proteids. Peptonizing the milk mixtures is also often useful.

While the proportions just given are those best suited to the average case, many do not do well on them. In such cases various modifications must be tried until one is found which suits the individual infant. Unfortunately, it is not infrequently impossible to find such a modification and the infant continues to lose and finally dies. In cases which improve it is usually possible to gradually increase the amount of fat in the food and finally work up to the proportions which are suitable for a normal child of the same age. In beginning treatment it is best to give small amounts of food at short intervals. It is often advisable to give proteids apart from milk. They are best given in the form of egg-albumin or beef-juice. Somatose, in doses of five or ten grains, mixed with water, is also useful.

Due attention must be paid to cleanliness and to the maintenance of an unusual supply of fresh air and sunlight. It is especially important to keep up the body temperature, as the vitality of these infants is very low. They must not be handled more than is absolutely necessary and all excitement must be avoided. No point in the hygiene and nursing of these cases is so small as not to be of importance. Stimulation, preferably in the form of brandy or whiskey, is often necessary. Complications must be treated as they arise.

THE TREATMENT OF CYSTITIS.[1]

BY CHAS. CHASSAIGNAC, M.D.,

OF NEW ORLEANS;

PROFESSOR OF GENITO-URINARY AND RECTAL DISEASES, AND PRESIDENT OF THE NEW ORLEANS POLYCLINIC, ETC.

THE treatment of inflammation of the bladder depends to such an extent, in any given case, upon the form of inflammation to be dealt with that it is essential to consider the classification and etiology of the various clinical types of the disease. The principal ones are as follows: (1) Gonorrheal cystitis, (2) tuberculous cystitis, (3) cystitis of urethral stricture, (4) cystitis of prostatitis, (5) cystitis of calculus, (6) cystitis of tumor, (7) traumatic cystitis, (8) cystitis by direct infection, (9) descending cystitis, and (10) cystitis from ingestion of certain irritants. A mere enumeration of them suggests what is in all cases the first indication, namely, the removal of the cause when possible. However, before taking them up *seriatim,* it will be useful to study briefly the general indications applying to a greater or lesser degree to all forms of cystitis.

Rest.—In all instances quiet is of great utility. The more acute the case the more important is rest, preferably in the recumbent position, unless the base of the bladder chiefly is involved, when the patient may be more comfortable propped up in bed. Pressure on the bladder can be removed by causing the knees and thighs to be flexed. Under the head of rest should be included the avoidance of sexual intercourse and excitement of any kind.

Diet.—Bland food should always be insisted on. In very acute cases milk diet or a bread and milk diet is the most satisfactory. In less severe or more chronic cases, when a more liberal bill of fare can be allowed, very rich dishes and highly seasoned food should be strictly forbidden. Rhubarb, sorrel, asparagus, and truffles are considered harmful. Alcohol in any form is to be strictly prohibited. The patient should be encouraged to drink a large quantity of water in order to render the urine as bland and unirritating as possible. Alkaline waters are usually preferable, notably French Vichy and good lithia waters. Sugars and sweets are to be used only in

[1] Read before the Louisiana State Medical Society, 1901.

moderation. Tea, coffee, and tobacco should be avoided, if possible.

Laxatives.—The bowels should be kept gently open by means of mild laxatives and their condition must be watched, especially when opiates have to be administered. Any drug can be resorted to which acts gently on the patient, it being advisable to change the preparation from time to time if something has to be given often. Enemas are very useful and should be used either in conjunction with laxative remedies or to replace them.

Baths.—Hot baths, full or only to the waist, are of great utility by producing relaxation and relieving tenesmus. They should be given frequently, but should not be protracted. They assist also in diluting the urine by causing some absorption of water.

Hot Applications.—Heat applied over the bladder by means of water-bags, or poultices, or compresses wrung out of hot water, produces a great deal of comfort, diminishing pain, tenesmus, and frequency of micturition. Hot-water enemas serve the same purpose, in addition to unloading the bowels.

Intravesical Irrigations.—Frequent washing of the bladder with warm, mild antiseptic fluids often prove curative as well as palliative. They can be made either by means of the catheter or by the Janet method directly through the urethra by pressure into the bladder. I am partial to the latter on account of its convenience and also because contact with any sort of catheter is likely to prove painful and irritating. In either instance, mild solutions should be used with great care. In acute cases the bladder should never be distended. Fluid should be allowed to run in only to the point of toleration, then evacuated, after which more can be introduced and expelled in succession for a number of times, unless pain is provoked. In chronic cases more in proportion can be allowed to enter, as the bladder is a little more tolerant and it is often useful to bring about a gradual distention of the bladder; the injection or irrigation then becomes a sort of gymnastic exercise.

Alkalines.—Their administration is useful in neutralizing the normal acidity of the urine, hence diminishing its irritating properties. They should not be pushed beyond producing neutral urine and should be omitted in cases in which the urine is already alkaline. Citrate of potassium, benzoate of sodium, and the alkaline waters already mentioned are probably the most valuable.

Anodynes.—The sensitiveness of the bladder and its frequent contraction from inability to retain any amount of urine provoke a good deal of suffering, particularly in acute cases, and the administration of anodynes becomes imperative. If the remedy can be given by the mouth, a good combination is codeine with hyoscyamus; to this can be added mild diuretics or any special medication indicated. If there is nausea or other contra-indication to administration by the mouth, suppositories of opium and belladonna can be introduced into the rectum at reasonable intervals; they act as a rule very promptly and efficiently, partly no doubt from their propinquity to the diseased organ. The danger of leading to a drug habit must be borne in mind, especially in cases having a tendency to chronicity, and the constipating effects must be combated as already mentioned.

Antiseptics Internally.—Most of the so-called urinary antiseptics can serve us in the majority of cases. They must be given cautiously in order not to cause irritation of the stomach and especially of the kidneys. Their relative value has been frequently discussed of late and the most effective are generally thought to be salol, urotropin, boric acid, and benzoic acid (or benzoates). Salol and boric acid in combination are my favorites. Urotropin may be added or used alone. It is often effective, but may provoke or keep up frequency in micturition.

All the above remedial measures are useful in all forms and at all stages of cystitis. They are more imperatively indicated in the acute cases and in the most acute have to be relied upon to produce a modification of the inflammation and the most painful symptoms before more special medication can be resorted to. This being understood, we can review rapidly our clinical classification and study special indications. The latter cannot be much more than mentioned as any detailed consideration would lengthen this paper to an unwarranted extent.

Gonorrheal Cystitis.—The inflammation is nearly always due to the invasion from the urethra of the gonorrheal poison. Hence, in addition to general measures already mentioned, our efforts should be directed toward the inhibition or destruction of the specific organism. By the mouth we can give salol, the salicylates or boric acid. Oil of santal usually proves soothing, as it does in the urethra. Locally, irrigations of hot solutions of potassium permanganate are about the most satisfactory. At first, small quantities at a time should be used and the solution should be very mild, 1 to 10,000 or 8,000 at most; as improvement is manifested, the palliative measures can be gradually dispensed with and the quantity and strength of the solution can be progressively increased.

Tuberculous Cystitis.—By the mouth, the preparations of creosote are indicated, in addition to general tonics that are not distinctly stimulating. Irrigations with solutions of bichloride of mercury and nitrate of silver have been recommended, as well as instillations of small quantities of strong solutions of the latter. Injections of emulsions of iodoform have been found useful. The possible benefits from change of climate and from the exhibition of some of the modified tuberculins, as in other manifestations of tuberculosis, should not be neglected. The prognosis, however, is not good. If a cystoscopic examination should reveal the presence of ulceration, the patient's general condition being fair, a suprapubic cystotomy would be indicated in the

male. This will facilitate curettage and topical applications; the latter procedure and the applications can be made in the female after dilatation of the urethra.

Cystitis of Urethral Stricture.—The constriction, impeding the normal outflow of urine, increases the contractions of the *detrusor urinæ* and produces congestion; partial retention usually occurs to aggravate matters and the inflammation which always exists in the urethra back of the constriction readily spreads to the bladder proper. In addition to general measures, treatment of the stricture includes everything. According to circumstances, gradual dilatation, electrolysis, internal urethrotomy, or external urethrotomy can be selected. Complete evacuation of the bladder must be assured promptly; the more severe the cystitis and the longer its duration, the more we should incline toward operative measures and do them promptly and radically.

Cystitis of Prostatitis.—This is analogous to that produced by stricture of the urethra and the indications are the same, except, of course, that the operative measures must be directed to the prostate. The latter can be enucleated, preferably by the combined suprapubic and perineal method, or can be acted upon by the cautery after the method of Bottini. Much can be done in palliation by relieving the bladder of residual urine by means of careful catheterization at proper intervals, by irrigations, and by the cautious administration of urinary antiseptics.

Cystitis of Calculus.—Removal of the offending body either by lithotrity or suprapubic cystotomy is the treatment. If the cystitis is very pronounced and of long standing, we have a strong argument in favor of the cutting operation.

Cystitis of Tumor.—If the case is operable, removal of the tumor by the most available route and method removes the cause and general measures do the rest. If the tumor cannot be successfully removed, palliation alone is possible. In malignant tumors, if circumstances justify it, the bold surgeon can consider the removal of the bladder with transplantation of the ureters, but these growths almost invariably recur.

Traumatic Cystitis.—This form of cystitis is due to injury from external sources, such as gunshot, incised or punctured wounds, lacerations from fragments of fractured bone, or to internal injury, such as violent instrumentation, and the treatment must be based upon the principles of general antiseptic and aseptic surgery. The special indication is to keep the organ well drained in order to avoid complications due to leakage of urine. General measures already mapped out are useful and often necessary.

Cystitis by Direct Infection.—As this is generally provoked by the entrance of a poison of some sort directly into the bladder by means of an unclean catheter, bougie, searcher, trocar, or cystoscope, the special feature is more in the direction of prevention than of cure. All vesical instruments, and all urethral instruments as well, should be thoroughly sterilized before introduction. The urethra should be thoroughly irrigated, the glans and meatus receiving careful attention. The surgeon's hands should be surgically clean. Special attention should be paid to the lubricant used. After harm is done, ordinary measures will suffice, adding thereto any special feature made necessary by the character of the infection if such be specific. As an illustration of my meaning, I may cite a case of cystitis caused by the introduction of a sound previously used in a case of chronic gonorrhea and not properly sterilized. Such would necessarily have to be treated like any other attack of gonorrheal cystitis. The bacillus coli communis has been known to infect the bladder by direct penetration therein. Antiseptic irrigations, assisted by general measures, control the inflammation.

Descending Cystitis.—Inflammation in the kidney, the ureter, or both, traveling downward finally invades the bladder, or the secretion itself directly produces cystitis which, be it said parenthetically, often clouds the diagnosis as much as the urine. Treatment of the bladder can only give temporary results. A cure can follow only a healing of the ureter and kidney or the removal of same if necessary.

Cystitis from Irritants Taken Internally.—This form is easily controlled by a discontinuance of the drug or other offending substance and by the general measures to which allusion has repeatedly been made. Turpentine and cantharides are most likely to offend. Their use internally or over the skin must be watched and must be discontinued at the first sign of vesical irritation. A sometimes puzzling manifestation of the effects of cantharides follows the enjoyment of papabotes (a southern sand-piper) that have indulged in a copious meal of Spanish flies. I have frequently seen patients, otherwise well, very much alarmed by a sudden and severe attack due to this cause.

MEDICINAL TREATMENT OF DIABETES MELLITUS.[1]

BY ARCHIBALD DIXON, M.D.,
OF HENDERSON, KY.

SINCE the classical monograph of Von Noorden and the exhaustive articles by Pavy, Williamson and Naunyn, it would be not only an act of supererogation but also one of extreme vanity to attempt to discuss the subject of diabetes mellitus in all its phases. It will suffice to say that diabetes "is a disorder of nutrition in which sugar accumulates in the blood and is excreted in the urine, the daily amount of which is greatly increased."

The cause of the disease may be briefly stated as due to altered or faulty metabolism. I shall not take up the general treatment of this most intractable disease, but will merely give some results which have followed the administration of

[1] Read before the Ohio Valley Medical Association, Henderson, Ky., May 13, 1901.

a certain remedy to a number of patients in my charge.

In speaking of the treatment of diabetes even from a medical standpoint, one can hardly afford to ignore the question of diet. The main object to be accomplished is the reduction of the carbohydrates as far as may be. It is not possible to do this absolutely for any length of time, nor indeed do I think it necessary, but by a careful selection of food the amount of starch taken can be reduced to a very small quantity. It is, of course, necessary in each case to write out and give to the patient careful directions as to diet, but we all know how distasteful a strictly diabetic diet becomes and how difficult a matter it is to confine a patient to it, in fact, I think this is rarely, if ever, done, except in cases of exceptional severity when the patient is himself alarmed. In mild cases when the amount of sugar is small and is, as so often happens, associated with gout, all that is needed is that the patient be given a diet suited for that malady. We often encounter cases in which although much starch occasions glycosuria, a small quantity will not do so, the amount of the disturbance of the glycogenic function being slight. It is therefore important to discover in case of any individual patient how much, if any, starch he can consume without increase of sugar in the urine. He should be allowed to take a certain small quantity of starchy food and if no increase of sugar results a little more may be given, and in this way we may learn what quantity of starch it is safe to give. In a number of my cases there was no strict adherence to rules of diet, and in two cases the patients took both bread and potatoes and other interdicted things as well.

One or two successful cases are not enough to warrant judgment of the merits of any drug; case after case must yield to it after obstinately resisting other therapeutic measures before we can confidently state its worth. If a remedy can be found to control the excessive loss of fluid which is going on in diabetes and to improve the general condition of the system, in other words, to correct a faulty metabolism, we may reasonably hope, with a careful diet and regimen, to prolong life for many years in comfort, if not to cure disease itself. Such a remedy I believe we have in a combination of bromide of gold and arsenic. It is probable that the deductions made by Stucky after many experiments are correct and that in the combination of gold and arsenic we have an agent which is a direct cerebrospinal stimulant, one that stimulates the capillary system though its action upon the central nervous system, thereby being indirectly a heart stimulant. By this combination there is developed an action entirely different from either gold or arsenic separately, so far as we know at this time, which by its glandular stimulating properties aids elimination, feeds the nervous system, thereby checking waste, stimulates the cord, brain, and glandular system, thereby stimulating digestion, and by its reconstructive power lessens disturbances of metabolism

The results obtained in the following cases go far toward establishing as facts the claims made.

Case I.—G. B., aged fifty-eight years, former railroad man, experienced good health till the fall of 1899, when he began to notice a lack of energy and an increased action of his kidneys; however his appetite was good and he slept fairly well and perhaps gained in flesh. In April, 1900, he was told by a medical man that his kidneys were sound, although at this period he passed an excessive quantity of urine. For many years he was addicted to drinking a great deal of beer, but had lately reformed. During the summer he became very weak and languid, lost flesh and had no appetite. In November last, when I saw him for the first time, he was so feeble that he could with difficulty walk across the room and was very worn and emaciated. He was afraid to eat from the extreme flatulence and inability to digest food. The action of the heart was weak. The liver was appreciably enlarged and there was considerable fluid in the peritoneal cavity. The superficial veins of the abdomen were enlarged, the legs were anasarcous, shining and pitting on pressure. The specific gravity of his urine was found to be 1045 and it was loaded with sugar. During the day and night he passed about twelve pints of pale straw-colored urine. Nitro-muriatic acid, with taraxacum and gentian, was ordered and he was directed to drink a little Scotch whiskey and water. In addition he was to have ½ grain of codeine night and morning, which was to be gradually increased till effect. December 10th, as he was not making any satisfactory progress, I prescribed arsenauro in 5-drop doses three times a day, to be increased 2 drops each day until further orders. In ten days a remarkable change for the better had set in; the urine was reduced in quantity and the appetite and strength improved. He was now taking 23-drop doses 3 times daily, which was directed to be continued without further increase.

URINE PASSED IN TWENTY-FOUR HOURS.

Date.	Quantity.	Specific Gravity.
Nov. 12, 1900	12 pints,	1045
Dec. 10, 1900	11 "	1040
Jan. 14, 1901	6 "	1030
Jan. 28, 1901	5 "	1024

February 3d.—He has increased fifteen pounds in weight and looks altogether another man. His liver is greatly reduced in size and the abdominal veins are much less prominently marked. No fluid can be detected in the cavity of the abdomen and the tympanites is very slight. There is scarcely a trace of edema in the legs.

In March the patient was so far improved as to consider himself well.

Case II.—H. L., coal-dealer, aged forty-seven years, was seen by me December 11, 1900. He had all the essential symptoms of diabetes, polydipsia, polyuria, polyphagia, and in addition he complained of headache, pains in the lower extremities, dryness of the mouth, etc. Knows nothing of his family history; formerly drank to excess, but has been strictly temperate for the last ten years. Urinary examination: Specific gravity, 1039; sugar present in large quantity; albumen, none; quantity passed in twenty-four hours, 8 pints. He was given the usual instructions in regard to diet and bromide of arsenic and gold ordered in 5-drop doses three times daily, each dose to be increased 2 drops for a week, at which time he was to report.

December 28th.—Urine passed in twenty-four hours, 5 pints; specific gravity 1030, sugar present, but in reduced quantity; thirst greatly lessened and other symptoms improved.

There was steady and continued improvement in this case and the latter part of February, 1901, he was discharged, with instructions as to restrictions in diet. During almost the entire treatment the patient had eaten potatoes and violated the rules laid down by eating ordinary bread frequently. At the time of writing he says he is perfectly well.

In 1877 Lancereaux demonstrated the existence of a form of diabetes mellitus found in conjunction with pancreatic lesions. This, he claimed, constituted a special and distinctive variety of diabetes characterized by considerable emaciation, with polydipsia and polyphagia, by peculiar alvine evacuations, and especially by a very rapid evolution. The study of Lancereaux has been made the basis of further investigations which have led to the discovery of new facts in this connection.

Various kinds of pancreatic alterations may be regarded as leading to this kind of diabetes. They may be primary lesions or they may be the secondary result of the presence of calculi or they may be caused by compression of the ducts due to neoplasms. In all such cases there appears to be a total abolition of the pancreatic function. This suppression of a digestive function is revealed by special symptoms which may occur previous to the usual diabetic phenomena; these ordinarily consist of grave intestinal disturbances, vertigo, vomiting and frequently jaundice. True, these symptoms after a while disappear, but they leave the patient in a condition of profound debility.

Soon, however, the essential symptoms of the disease begin to manifest themselves and are rapidly established, reaching an acme in a few weeks or months. Diarrhea is often if not always present, the stools having a greasy, creamy appearance. Emaciation is rapid and in a few months the patients lose successively their physical, intellectual and genital powers. Then complete prostration and profound marasmus set in, to which there is often added hectic fever with symptoms of consumption.

The theory of Lepiné of Lyons is that the pancreas produces a ferment which enters the circulation and causes a breaking-up of the grape-sugar molecules within the blood. He calls this "glycolytic ferment." After extirpation of the pancreas this ferment is not present; the sugar therefore accumulates undestroyed in the blood, and from this hyperglycemia so produced glycosuria results. Mering and Minkowski do not accept this theory *in toto*, but after excluding all other possibilities formulate the following hypothesis: "Either some substance which has an injurious influence upon the conversion of sugar collects in the organism after extirpation of the pancreas, or else after this operation there is some substance wanting, or some function is abolished which under normal conditions serves to facilitate the conversion of carbohydrate bodies."

The following is a typical case:

Mrs W., aged fifty-nine years, Jewess. Father died from kidney trouble; other family history unknown. Consulted me October 29,1900, for a diarrhea which had been present for some time and which had resisted the ordinary home treatment. The stools were described by her to be frequent, painless and not large, greasy and creamy in appearance. Latterly the stomach had become disturbed and there was occasional vomiting. She also complained of swimming in the head and there was slight jaundice. Tongue was clean, red and slick; abdomen tympanitic and the area of liver dulness larger than normal. Appetite was fairly good, but there was progressive loss of flesh and energy. Gastro-intestinal indigestion was diagnosed and appropriate treatment given. High enemas were ordered to be taken daily and strict rules of diet urged. Improvement was slow and unsatisfactory; loss of weight continued, though not so rapidly as before. In December the diarrhea became much better and there was less gastric disturbance; the jaundice had disappeared and there was only occasional vertigo, slight in character.

I saw this patient no more until January 15, 1901, when she again consulted me, but for an entirely different set of symptoms. She now complained of great thirst, parched mouth and excessive micturition; in fact, she gave all of the essential symptoms of diabetes. Upon examination the urine was found to have a specific gravity of 1042 and sugar was present in large quantity—3 per cent. She complained of great weakness and was irritable and cross. An especially annoying symptom was excessive and almost constant pruritus due to eczema of the vulva.

Treatment was bromide of gold and arsenic (arsenauro), 5 drops after each meal, to be increased 2 drops to the dose each day. She was given the usual written directions as to diet. Notwithstanding flagrant violation of orders, the patient eating ordinary bread and potatoes in addition every day, the improvement in her case was marked. The decrease in the quantity of urine passed and in the amount of sugar present was evident the first week. In three weeks there

was barely a trace of sugar and the urine was much reduced in quantity.

March 15th.—Urine normal in quantity; sugar, negative. The eczema has disappeared and there is no pruritus. Patient much improved in strength and has gained seventeen pounds in weight; says she is well and to all appearances is so. She was dismissed with instructions to continue the drug in 5-drop doses, three times daily for a month, and to avoid carbohydrates for six months.

The number of drugs which have been recommended in the treatment of diabetes is legion—an evidence of the small benefit of any individual one. Even the most optimistic believers in materia medica, rendered cautious by oft repeated disappointments, become skeptical when any one praises a remedy for diabetes. The question is not whether many drugs are not useful and even necessary in diabetes in order to meet one or another of the special indications or to combat the complications, but rather whether we possess any remedy which can increase the energy of the sugar-destroying function. It often seems as though we did possess such a remedy in the combination of gold and arsenic, but favorable results are rarely observed when the rule of making no change whatever in the diet either before, during or after the administration of the remedy under trial, is strictly adhered to. A number of patients under treatment by me with these drugs have followed no rules of diet; others have frequently violated the rules given and have partaken of carbohydrates to a greater or less extent, but notwithstanding have been given great comfort; their self-confidence has been increased, worry diminished, sleep restored, and the subjective symptoms greatly improved—and all of these are unquestionably factors of far-reaching importance in regard to glycosuria.

MEDICAL PROGRESS.

Bipolar Version.—In spite of the greater infantile mortality, H. D. FRY (*N. Y. Med. Jour.*, Aug. 17, 1901) prefers bipolar version with slow extraction to *accouchement forcé* in the treatment of placenta prævia. The advantage of the version is the ability to perform it successfully with very little dilatation and consequently with less loss of bood. At the same time there is greatly decreased maternal risk.

Treatment of Diabetic Coma.—Life-saving potency has been attributed to various methods of treatment of diabetic coma; among these methods is the administration of large quantities of sodium bicarbonate. In an analysis of reported cases, L. SCHWARTZ (*Prager med. Woch.*, Aug. 1, 1901) accepts but four cases as beyond criticism; these cases were children, to whom an exceptionally large quantity of soda can be administered in proportion to body-weight. Three cases of diabetic coma were observed by Schwarz. In two of these cases a sodium salt of gluconic acid was added to the usual alkaline treatment, with successful outcome; the third case was treated by the alkaline method alone, with fatal issue. Gluconic acid appears to have the property of diminishing the production of the pathological substances which cause diabetic coma. In this connection the close relation between gluconic acid and the carbohydrates is alluded to. In acetonuria without coma, a given quantity of gluconic acid will control far better than an equal amount of grape sugar, the appearance of acetone in the urine.

Disinfection Researches with Lysoform.—Among the disinfectants used by clinicians during the past few years lysol has taken a fairly prominent place. It is but slightly irritating when employed in a one- to three-per-cent. aqueous solution and possesses a tolerably high disinfecting power in such dilution. Its poisonous properties have, however, somewhat limited its use. Lysoform, a formalin derivative, has recently been advocated as a disinfectant for clinical use on account of its non-poisonous properties which are combined with a fair degree of bactericidal power. It is a yellow fluid of an oily consistency, freely soluble in water and alcohol and possesses none of the irritating properties of formalin. It is odorless. When mixed with ordinary water the solution is somewhat cloudy in appearance, but this has no significance. SYMANSKI (*Ztschrift f. Hyg. u. Inf.*, July 31, 1901) has added urine to ordinary bouillon and incubated this for two days. This mixture was then in a state of active putrefaction. Microscopical examination showed the presence of both spore-forming and non-spore-forming organisms. He then tested the comparative power of lysoform and lysol against these organisms. In a separate series of investigations he added from .01 c.c. to 1. c.c. of these agents to 100 c.c. of the putrefying mixture, protected this from the light and maintained it at the ordinary room temperature. After twenty-four, thirty-six and seventy-two hours respectively "platings" were made from this into glycerin-agar. None of the lysoform plates were sterile, while the lysol plates taken from the .5 c.c. to 1 c.c. mixtures did not show the presence of any organisms. The bactericidal power of the stronger lysoform and the weaker lysol solutions were about the same. The deodorizing power of lysoform was much greater than that of lysol. Experiments with highly albuminous liquids showed that in such lysoform possesses very little antiseptic power, plates made from five-per-cent. solutions showing about 5,000 colonies per plate. Tested on spore-forming anthrax bacilli of moderate resistance, plates from two-per-cent. to three-per-cent. lysol solutions were sterile and the same result was obtained with three-per-cent. to five-per-cent. lysoform solutions. Inoculation experiments on mice and guinea-pigs demonstrated that lysoform possesses very little poisonous properties for them.

Cytodiagnosis in Meningeal Disease.—Since 1896 means of cytodiagnosis have been persist-

ently sought, and the method has been applied to various pathological states. X. LEWKOWICZ (*La Presse Méd.*, Aug. 17, 1901) has studied the cellular content of the cerebrospinal fluid in cases of meningitis. While Widal believes that normal cerebrospinal fluid contains no cellular element, Lewkowicz asserts that a few lymphocytes may always be found in such fluid. The latter differs with Widal also concerning the character of the cells found in tuberculous meningitis. According to Widal these are always lymphocytes, while Lewkowicz states that in 20 per cent. of the cases examined by him polynuclear cells were chiefly present, with only a small representation of lymphocytes (11 to 16 per cent.). The question is asked whether a cancerous tumor of the meninges or the changes occurring in early stages of general paralysis do not probably cause characteristic modifications of the cerebrospinal fluid and its cells.

Indications for Operation in Gastric Ulcer.—As the risks of operation diminish, we have frequently to readjust our ideas as to the persistence with which medical treatment must be tried before resort is had to surgery. The present indications for operation in cases of gastric ulcer are stated as follows by A. T. CABOT (*Boston Med. and Surg. Jour.*, Aug. 29, 1901): (1) Acute hemorrhages should rarely be treated by operation; the results of interference have not been good, while satisfactory results have followed medical treatment; frequently repeated hemorrhage, even if severe, will demand operative treatment. (2) Small frequent hemorrhages, threatening anemia, indicate operations. (3) Perforation of the stomach, whether acute with general peritonitis, or chronic with adhesions and perigastritis, demands operation. (4) When an ulcer runs a chronic course and gradually diminishes the patient's capacity for work and enjoyment of life, an operation is indicated, especially when the patient is dependent on his daily work for support and is unable to regulate closely his diet.

Metastatic Choroiditis in Pneumonia.—This is not a very frequent complication of pneumonia, but six cases are reported by C. S. BULL (*Med. Rec.*, Aug. 31, 1901) and it is of such grave import that the condition should be readily recognized. The disease is characterized by pain in the eye and head, intense vascular congestion and rapid and total loss of sight. Intra-ocular pressure is at first raised and then diminished much below normal even when no perforation occurs. The course is from three to six weeks and the prognosis bad, the case ending with total blindness and a shrunken eyeball. The lesion is usually bilateral, signifying the constitutional character of the infection.

Agglutinating Substances.—These have of late been the subject of much investigation and many hypotheses have been advanced in regard to them. It has been held that these substances are present only in the superficial layers of microorganisms and that the process of agglutination is nothing more than a variety of coagulation. F. C. HARRISON (*Centblt. f. Bäk.*, July 31, 1901) has recently studied this subject along somewhat new lines. He experimented with the pyocyaneus and typhoid bacilli by dissolving their superficial layers, but leaving the internal nuclear portion intact. His work shows that the agglutines exist entirely in the external layers of these organisms and that when these are removed the remaining portions are incapable of giving a reaction even with a very powerful serum. He thus endorses and amplifies Nicolli's hypothesis that agglutination consists in the coagulation and coalescence of the external layers of agglutinating organisms.

Symptoms and Treatment of Nitrobenzol Poisoning.—Reliable symptoms of nitrobenzol poisoning are the characteristic odor about the mouth and the associated cyanosis. When large doses are taken stupor is present, or even total loss of consciousness, together with a rapid pulse and respiration. A latent period of about 30 minutes follows the administration of this poison by mouth, owing to its insolubility in water and in gastric juice. An occasional symptom is hematogenous icterus, and numerous nervous symptoms are possible, including headache, vomiting, ringing in the ears, vertigo, pupillary alterations, palpitation, stammering, convulsions. In cases cited by V. SIMERKA (*Wien. klin. Rund.*, Aug. 11, 1901) fatal doses were respectively 150, 20, 15 grams. In treatment the first essential is prompt stomach-washing. Wine or milk must not be given on account of the solubility of nitrobenzol in fats and in alcohol.

Typhoid Bacilli in Sputum.—The sputa of eleven typhoid patients were examined for typhoid bacilli by P. EDEL (*Fortschr. d. Med.*, 1901, No. 14). In ten cases the patients suffered merely from a complicating bronchitis and typhoid bacilli were not found. In the eleventh case a bilateral pleural exudation occurred at the end of the third week. For several days following the development of the pleurisy the sputum continued bronchitic in character and contained no typhoid bacilli; the sputum then became hemorrhagic, and during ten days typhoid bacilli were found three times; later examinations were negative. The bloody sputum in this case did not resemble the characteristic rusty sputum of croupous pneumonia, but contained an admixture of bright red blood.

Actinomycosis Hominis.—A very unusual and interesting case of actinomycosis diagnosed before death is reported by G. FUTTERER (*N. Y. Med. Jour.*, Aug. 24, 1901). For seven years the man had suffered from attacks of pain in the epigastrium, severe in character, lasting a few hours and sometimes followed for a few days with clay stools. An operation four years previously had disclosed a caseous mass in the right epigastrium, which was removed and the wound healed quickly. Later a laparotomy showed many abdominal adhesions and some caseous material and persistent sinuses followed. For a year past, well-developed symptoms of phthisis pulmonis

have been present. In the discharge from the sinuses ray fungi were found, but none in the sputum. Autopsy showed that the liver substance, especially of the right lobe, had been almost entirely destroyed and that the process at this point was evidently continuous with a destructive lesion which involved nearly the whole right lung. It is supposed that the initial lesion was situated in that lung. Two yellow nodules were also found. At the bases of the tricuspid valves, developing along the course of the coronary artery of the heart. A distinguishing feature of peribronchitic actinomycosis is thought to be found in the sharply defined, sulphur-yellow rings which tend to grow inward and involve the lumen of the bronchus rather than the surrounding lung parenchyma, as happens in tuberculosis.

Treatment of Delirium Tremens.—Signs which can be relied on as indicative of approaching delirium tremens have long been sought. J. F. PERRY (*Boston Med. and Surg. Jour.*, Aug. 22, 1901) regards no sign as absolutely certain. Exceeding nervousness in a hard drinker is suggestive. A more valuable premonitory sign is said to be a more or less continuous dilation of the pupils for twenty-four hours before delirium commences. At Blue Hills Sanitarium reasonable quantities of their accustomed liquor are allowed to patients just admitted as chronic alcoics; the final withdrawal occurs on the third or fourth day, with gradual diminution of the supply during the intervening period. As a substitute for alcohol, ammonia, camphor or hyoscyamus is given. For excessive muscular tremor opium in small doses is administered every two hours. At the first sign of trouble an effort is made to get the patient to sleep; if six or eight hours of sleep can be obtained the delirium will usually be dissipated. Perry commends the use of small doses of chloral hydrate, at half-hour intervals, except where contra-indicated by the cardiac condition. Where chloral fails, chloralamid and paraldehyde will usually do no better, hyoscine hydrobromate may be more satisfactory, and in desperate cases musk is effectual, though expensive. When medication by mouth is refused, apomorphine, hyoscine and morphine are most useful hypodermatically. A delirious patient must not be disturbed when sleeping.

Bactericidal Power of Rabbit Serum in Anthrax.—According to the exponents of the alexin theory, natural immunity is due to the presence in the blood of certain protective substances. This is established by the fact that if bacteria are introduced into blood or blood serum *in vitrio* an inhibition of their growth is seen to take place and if the number of organisms so introduced is very small they very soon perish. The serum of different animals is known to vary in its bactericidal power according to the micro-organism with which it is brought into contact. The power of rabbit serum over anthrax bacilli has recently been studied by M. WILDE (*Z'tschrift f. Hygiene*, July 31, 1901). He investigated the effect of active and inactive rabbit and cow serum upon anthrax and typhoid bacilli and demonstrated that both active and inactive rabbit serum have an injurious action on anthrax bacilli which they do not possess for the typhoid organism and that cow serum has no deleterious effect upon either bacillus. His experiments were conducted by mixing typhoid and anthrax bouillon cultures with the various sera and subsequent "plating" in glucose-agar. In the anthrax infection of rabbits the great accumulation of the bacilli in the blood-vessels occurs in the death agony, during which the bactericidal power of the blood is either entirely lost or much diminished. In addition to the alexins there exists in the blood of most rabbits still another substance, probably only injurious to the anthrax bacillus, which is not destroyed, as are the alexins, by one-half hour's heating at 57° C., but which for its destruction requires twenty-four hours' exposure to this temperature.

Chromatopsia.—The production of chromatopsia may be due to a variety of causes, a consideration of which must precede intelligent treatment of this condition. As enumerated by H. CHALUPECKY (*Wiener klin. Rund.*, Aug. 11, 1901) the chief etiological factors are (*a*) general diseases: Here there may be a genuine anatomical foundation for the condition, as in icterus, or there may be a functional retinal disturbance due to malnutrition, as in exhausting febrile diseases. Failure of retinal adaptation, as yet vaguely understood, occurs also in hysteria, epilepsy, migraine; (*b*) intoxications; there may exist here a disturbance of the irritability of nerve-endings, due to direct action of the poison, or a failure of retinal adaptation connected with abnormal behavior of the retinal pigment; (*c*) diseases of the fundus; (*d*) dilatation of the pupil; (*e*) exposure to dazzling light. The existence of a special cortical center for color-sense, through irritation of which chromatopsia might be explained, cannot be accepted, according to this author, upon either practical or theoretical grounds.

Measurement of the External Urethral Orifice.—For the purpose of cystoscopic examination, catheterization of the ureters and the like in females, it is important to know what is the largest cystoscope which can be used without injury to the urethra. In a normal urethra the greatest resistance is met with at the external orifice. Measurements of the external urethral orifice were made by G. BROWN MILLER (*Johns Hopkins Hosp. Bull.*, Aug., 1901) by means of the urethral calibrator of Kelly in 100 cases. The smallest orifice found measured .4 mm.; the patient was a woman who had borne eight children. Two urethræ, likewise in multiparous women, measured 12 mm. Average diameter of the meatus in 100 cases was 7.59 mm. Average diameter of meatus in multiparous women was 7.83 mm.

Diphtherial Infection from Well Persons Carrying Bacilli.—A case which illustrates important points concerning the contagiousness

of diphtheria is reported by F. A. WHITE (*Boston Med. and Surg. Jour.*, Aug. 29, 1901). The interesting features are as follows: Virulent bacilli were present for eighty-five days in the throat of a child who had a mild attack of diphtheria. Three months after the child's illness, after the premises had been twice fumigated, virulent bacilli were present in the throats of two out of four of the child's associates; these two associates did not have diphtheria, although they carried virulent bacilli in their throats for a long time. The persons not showing bacilli in the throat were of ages when infection is less likely to occur (six months and twenty-five years); those showing bacilli were four years and eighteen years respectively. A child of four years was exposed for two days to the children having bacilli, and within five days this child developed diphtheria.

Ether in Removal of Ceruminous Plugs.—To remove ceruminous plugs from the external auditory canal various means have been used to soften or partly dissolve the mass. Alcohol, glycerin and salts of sodium and, of late, peroxide of hydrogen have been employed. E. L. MEIERHOF (*N. Y. Med. Jour.*, Aug. 24, 1901) has found that undiluted sulphuric ether poured from a small bottle or pipette acts in a few seconds so that the most gentle syringing is successful. No dizziness or ill-effects have been caused by this method, but the author recommends that a mixture of equal parts of alcohol and ether be used.

Suppurative Pyelophlebitis. — Comparatively little experimental research has been instituted with respect to this condition. The major part of the work hitherto done has been conducted by the employment of aerobic methods the results of which are non-conclusive in regard to fetid suppurative processes. CHARLES NORRIS (*Jour. Med. Research*, July, 1901) reports a case in the study of which anaerobic methods were chiefly employed. The disease ran an acute course, the clinical symptoms being daily chills, fever, delirium and stupor. At autopsy there were present calcareous degeneration of the coronary arteries, moderate congestion of the spleen and parenchymatous degeneration of the kidneys. The duodenum and pancreas were adherent. The head of the pancreas and the adjacent fatty tissue were firm and indurated. There was a small abscess near the thrombosed pancreatic vein. The liver weighed 6½ pounds and both lobes contained numerous small abscesses. The pus was white, thick and fetid and showed on microscopical examination no ameba, but two kinds of organisms, *viz.*, cocci and long, slender bacilli. These organisms were both anaerobic and were with great difficulty isolated in pure culture. The cocci were similar to the micrococcus fœtidus of Veillon and an anaerobic streptococcus described by Menge and Kroenig. The bacilli were not identified. Inoculation experiments with cultures of these organisms some time after isolation were negative. Sections and cover-slip preparations of the hepatic lesions showed the presence of both of these organisms; this fact, taken in conjunction with the abundant anaerobic growth and the sterile aerobic plates, shows that these organisms were the primary excitants of the condition and not merely concomitant factors. The necrotic thrombosis of the portal vein indicates that the point of entry of these organisms was through the venous circulation of the liver.

Antitoxin Treatment.—Much bitter feeling has been shown by the advocates and enemies of the antitoxin treatment of diphtheria. It is largely due, no doubt, to the unwillingness of both parties to view the question from a broad standpoint. A. RUPP (*Med. Rec.*, Aug. 31, 1901) suggests that there has been proven to be a great difference between the scientific and the practical methods of treatment. It is now generally admitted that the diphtheria antitoxin antagonizes only the diphtheria toxin and the amount of toxin in a person is an unknown quantity. Other bacilli besides those of Klebs-Loeffler can produce clinical diphtheria. Thus the antitoxin becomes a remedy of rather limited utility, but, no doubt, of specific value in selected cases.

Bacteriology of Lobular Pneumonia.—This subject has been relatively little studied in adults, most attention having been given to the disease in children, especially as a sequel of diphtheria and the acute exanthemata. GEO. BLUMER (*Pro. N. Y. Path. Soc.*, New Series, Vol. I., No. 2) reports the study of 71 cases of which 53 were adults. A great variety of organisms were present, but the streptococcus and the colon bacillus were the ones most frequently found. When compared with the results of other observers the pneumococcus and the pneumobacillus were rarely found. The frequency of the colon bacillus is probably to be ascribed to agonal or postmortem invasion. In 21 cases in which this organism was present, 12 showed a general invasion. In 37 cases in which other bacteria to the exclusion of the colon were found, 23 showed a general infection. A study of the bacteriology of normal, congested and edematous lungs is interesting. Four normal lungs all showed the presence of bacteria and in 2 there was a general systemic invasion. Four edematous lungs all contained bacteria, while only one showed general infection. Fourteen out of 20 acutely congested lungs showed the presence of micro-organisms and in all but 6 there was also a systemic infection. Seventeen lungs, both edematous and congested, showed 15 which contained bacteria in 9 of which there was a general infection. These results indicate that in cases of simple congestion and edema, as well as in lobular pneumonia, general infection is the rule. These organisms are perhaps carried to the lung by the general circulation, but it is impossible to deny that the opposite may sometimes be the case. As in many cases no bacterial lesion aside from the pulmonary one is found, it seems that the lungs are much more frequently the portal of entry in general infection than is generally supposed and this often without marked pulmonary lesion.

THERAPEUTIC HINTS.

Detachment of the Retina.—De Wecker evacuates the subretinal fluid with a sharp-pointed instrument with two blunt edges and shaped like a broad needle. This is extended through the sclerotic and choroid at a place corresponding to the detachment, but not so deeply as to reach the retina. Preferably a position near the equator of the globe and between two recti muscles should be selected. When the needle is inserted, it should be turned slightly so as to open up the tissues and let the fluid escape. A firm bandage is applied and the patient kept in bed for eight or ten days. In some cases, the dorsal decubitus for four or six weeks, with a pressure bandage on the eye, has been successful. The cure is only temporary, the most favorable cases being those due to choroiditis, while the least favorable are due to posterior staphyloma.—H. R. SWANZY in "Diseases of the Eye."

Syphilitic Iritis.—Von Graefe was fond of the following formula in syphilitic iritis:

℞ Hydrarg. biniodid .... gm. 0.4 (gr. vj)
Potass. iodid ..... 6.0 (℥iss)
Aq. destillat. ..... 15.0 (℥ss)
Syr. aurant. ad. ..... 90.0 (℥iij)

Pleurisy.—In the beginning, we try to lessen the pain and dyspnea, writes ADOLF STRUMPELL, by mustard plasters, warm poultices dry cups, chloroform liniment or in severe cases, by morphine. If an ice-bag is well borne, it tends to check the inflammation. Painting with iodine is of doubtful efficacy. An iodoform ointment, one to fifteen, or iodoform collodion is of more value. If a large effusion has formed we may try to lessen it with diuretics, such as acetate of potassium, squill, potassium and sodium tartrate, etc. If there is weak heart action, infusion of digitalis is best. Drastic purgatives, sodium salicylate, pilocarpine or hot packs remove fluid, but are depressing. The benefit from iodide of potassium is greatly overestimated. Only when the effusion is large should it be removed by aspiration. To prevent loss of strength, the patient should get sufficient easily digested food.—"Text-Book of Medicine."

Otitis Media.—Adopting the belief that all catarrhal affections of the Eustachian tube and middle ear, are due to, or promoted by an inflammation of the nasopharyngeal mucous membrane, we must direct treatment to this. Nitrate of silver is the best remedy, applied in solution on some cotton wound about a cotton-carrier. The cotton should be squeezed out after dipping it in the solution, or this may run down and cause spasm of the glottis. The mop should have the terminal inch bent at right angles, then with the pharyngeal cavity illuminated by a forehead mirror and the tongue depressed, the patient draws in a long breath, then breathes it out slowly through his nostrils. This causes relaxation of the palate muscles, and at this moment the mop is passed high up behind the soft palate, first toward one Eustachian orifice, then across toward the other. If there is much mucus, the above procedure must, of course, be preceded by dry mopping till the mucous membrane is fairly clean. For children of from four to eight years, the author begins with a 15-grain solution of silver nitrate increased to 25 grains to the ounce, and makes the applications every second day.—A. H. BUCK, in "Diseases of the Ear."

Parenchymatous Keratitis.—Ir the early stages no irritants should be applied, but atropine should be instilled to prevent iritis or posterior synechiæ. Warm moisture, in the form of poultices or fomentations, promotes vascularization, and hastens absorbtion of the cellular elements which form the opacity. When the acute stage is ended, yellow oxide ointment, and in both stages massage may be used to disperse the infiltration. In severe cases mercurial inunctions for several weeks would be advisable, and in mild cases, iodide of iron, cod-liver oil, etc. The author has had good results from hypodermic injections of perchloride of mercury, gm. 0.0015-0.003 (gr. 1-40—1-20), once a day. Blisters to the temple and other counterirritation only increase the patient's discomfort, without good to the eye.—H. R. SWANZY, in "Diseases of the Eye."

Pterygium.—This, a triangular vascularized thickening of the cornea, is best left alone, unless it be very thick, or has invaded the cornea, or is progressive. For its removal a strong silk suture is passed through two needles; one is passed under the pterygium close to the cornea, and the other at its base, the ligature being drawn half way through. The thread is cut close to each needle and the ligatures thus made, tied tightly. In four or five days the pterygium comes away. The excrescence may be dissected off with scissors or a fine scalpel, or a good plan is to pass a strabismus hook under the ptrygium when raised from the sclerotic, and forcibly to separate the corneal portion by drawing the hook under it. The dissection is continued toward the base, where it is finished by two convergent incisions.—H. R. SWANZY, in "Diseases of the Eye."

Cirrhosis of the Liver.—Of all the symptoms the results of portal congestion deserve the most consideration. The bodily vigor should be promoted, and the patient enjoy complete physical rest. In the milder cases, depletion is encouraged by salines or small doses of calomel, gm. 0.03-0.06 (gr. ½-i), two or three times a day. In severe cases, more drastic remedies may be needed. Diuretics are of great value, and, besides potassium acetate, squill, etc., we may use copaiba or its resin the dose of the latter being gm. 1.0 (gr. xv) daily. In some cases this remedy has caused marked diuresis, and accompanying diminution of the ascites. If there is great local discomfort or dyspnea owing to ascites, paracentesis may afford relief. The application of an elestic bandage after the fluid is removed may retard its reaccumulation.—A. STRUMPELL in "Text-Book of Medicine."

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, SEPTEMBER 14, 1901.

THE PRESENT AND THE PAST.

IN THIS week's issue of the MEDICAL NEWS we present to our readers a short authentic account of the surgical features of the recent shooting of President McKinley, gathered by one of our staff from those in charge of the patient at Buffalo. We also publish a short summary of the illness of President Garfield and wish here to point out some of the more important differences which come to mind in comparing two somewhat analogous surgical incidents.

From the very beginning the cases are not comparable, within strict lines, but there are undoubtedly certain features which reflect a great difference in surgical procedures of the present day and those of twenty years ago.

The modern modes of conveyance whereby an injured man is readily and easily conveyed to a hospital equipped with all necessary appliances suggest one phase of difference in the treatment of President McKinley in contrast with that of President Garfield. No surgeon in a large city at the present day, save in the most extreme emergency, would think of examining a wound without the proper facilities and under the strictest antiseptic precautions.

Temporary expedients are rejected by the modern operator who has, under the teachings of antiseptic surgery, practically no dread of doing almost anything in the way of operative interference. The immediate and fearless opening of the abdominal cavity, with the direct desire of seeing with the eyes the damage done by the missile, marks another step which the methods of twenty years ago would not permit.

Should it subsequently become necessary to find and extirpate the bullet in President McKinley, physical science has placed in our hands the means whereby it may be located with an accuracy beyond a doubt. Had the use of the Roentgen ray been among the acquisitions of a former generation, it is more than probable that the secondary hemorrhage which took the life of President Garfield would not have occurred and that the removal of the bullet in the early days of his illness, and the appreciation of the injury to the bony structures of the spinal column, which also might have been detected by the use of these light rays, would have resulted in more radical and successful surgery.

The surgeons of that day lived up to the fullest of their opportunities. Let us be thankful that medical research has raised the level of the opportunities of the present generation to a much higher plane.

THE CASE OF THE PRESIDENT AND THE SURGICAL LESSON OF THE HOUR.

THE attention of the entire professional and, for that matter, the lay world has been fixed for the past week upon the case of President McKinley, and the grave problems involved in the prognosis of penetrating wounds of the abdomen and perforating wounds of the stomach.

The day has gone by for serious discussion of the necessity for promptly opening the abdomen in every case of penetrating wound of its cavity, occurring in civil life at least, with the view of repairing the damage inflicted upon its contained viscera by the perforating missile.

That the members of the surgical branch of the profession, whose judgment is at all worth having, have looked with the fullest approval on the course pursued by those who are in immediate attendance upon the President, goes without saying. The recognition of the fact that prompt operative interference held out the very best, if not the only chance, stands out as the pivotal point upon which every consideration of the case must turn. The surgeons met the first question at issue, namely, as to whether or not

the missile had invaded the peritoneal cavity, by immediately placing the patient upon the operating-table in the Emergency Hospital and enlarging the wound of entrance in order to at once and satisfactorily clear up this point. This having been decided in the affirmative, the next enquiry naturally arose as to what damage had been done to the important viscera. Here, again, a thorough investigation cleared up this vital point. There was no guess-work about it; no waiting for the occurrence of so-called symptomatic indications for further interference, or the cry of the nation to "do something" for the illustrious sufferer. It was done with that true instinct which marks the course of the modern surgeon, and done, too, with a celerity and skill that has won for the surgery of the century new laurels. For this is not merely a personal gain for the individual who happened to wield the knife, although to him should be given every praise, any more than the favorable result, which at the time of writing seems to be assured, is the gain alone of the patient himself. As the whole American nation and, in addition, the world at large, is the gainer by the life saved, so will the entire medical profession profit by the lessons taught and the victory won.

Surgeons who are brought face to face with the conditions which confronted those who, in the first hour following the infliction of the dastardly blow, were responsible to a vast and highly intelligent, and ofttimes hypercritical people, will realize what passed through their minds. As the eye took in at a glance the small blue-edged opening in the abdominal wall, so the mind instantly grasped the many possibilities of danger involved in the missile's fight. Visions of a bleeding vessel in the omentum or mesentery and rapid loss of blood, with great probability of collapse and death, and of perforated viscera with the only too-certain sequel of septic peritonitis, must have passed in rapid panoramic procession before them, to say nothing of the sight of the millions with pallid faces, surging hearts and bated breath, whose concentrated gaze was turned toward the little emergency operating-room in the Queen City by the lake. To wait for symptoms of internal hemorrhage and hope that they would not appear was but to lean upon a broken reed. To postpone the saving touch until assured that infection had actually taken place would be throwing away golden moments, render the effort to save futile, and, because of this futility, lay those responsible open to the well-merited charge of cowardice. Useless would it have been to attempt to justify such a course by quoting ancient statistics designed to show that the mortality of interference was almost, if not quite as large, as non-interference, for the answer would at once have been made that, of those who recovered without operation, there was no proof that vessels or viscera had been injured, and of those who died there was a failure of the realization of the importance of time as a saving factor, and the element of proper technic evidently wanting; proper criticisms involving underlying principles and supporting the contention that in former times this most important question had not been decided upon its merits. Neither could they have urged that, proof of infection being wanting, they were not justified in interfering. This would have been met by the assertion, based upon the experience of many a surgeon in abdominal work, that to wait for peritonitis to supervene would only be waiting for an excuse to put the finishing touches to a scene already tragic in the extreme. To have endeavored to escape criticism by the assertion that no vomiting of blood had occurred, and hence the stomach had not been injured would have brought to light from the literature the cases in which perforation of the stomach, as revealed by operation, had taken place and in which vomiting, and even pain had been absent. To have quoted the statistics of the late war would have availed but little, since experience shows that the rapid traversing of the tissues by a projectile from a high muzzle-velocity modern firearm is a far different matter compared with the damage inflicted by a cheap low muzzle-velocity and black powder-driven, soft lead missile which forces its way comparatively slowly into the tissues, adding the damage of structures crowded and forced against each other to that due intrinsically to the missile itself.

All these things are matters of thought in the surgical mind of to-day. And when the public appreciate to some extent what surgery has done for a well-beloved President, let the tribute of praise for the clear head, the cool judgment, the courage, and the skilful hand that were the instruments in the victory over the assassin's deadly purpose, mingle with the realization of what the medical profession is to the world.

As to the features of the case from the purely scientific standpoint, there is but little to dwell upon. The triumphs of aseptic surgery are com-

mon enough, and the experience gained since the then obscure Glasgow surgeon first promulgated his teachings have been slowly but surely pointing to the hour when the greatest living representative of the greatest of the nations of the earth should receive the benefit of those teachings in the most impressive manner. And, if it shall be that success waits upon the efforts of those who are striving for the life of the President, let it not be forgotten to acknowledge the obligation for the genius of the father of modern surgery, Joseph Lister.

THE GENESIS OF THE CRANK.

IT HAS long been admitted by alienists as well as by enlightened jurists that it is desirable, if not necessary, to make a distinction between mental aberration or insanity as viewed from the standpoint of a well-rounded mental activity and mental aberration which involves the principle of responsibility. Thus we have an individual afflicted with medical insanity who may never become insane from the legal point of view simply because society does not sufficiently suffer to render it necessary to recognize an abnormal member.

We would hold that there is no ideal mind that may be used as a scale by which other minds should be measured, but would formulate the idea that sound mental action is based upon the prevailing customs of the times and as such is a reflection of the development of the major portion of a large community.

Those who move in the center of the great stream of human progress, contributing their little to the advancement of individual development, we deem as healthy and sane-minded people; a few there are who dream dreams, both little and great, of future perfections; those who dream possible dreams are the geniuses of our social fabric; those whose dreams are impossible of all fulfilment make up the large body of fanatics and cranks of which we would speak.

It is almost a commonplace to say that most of us are for the most part products of our surroundings, our dreams are colored by those about us and it is to one phase of our environment that attention should be called if we would know of the genesis of the particular kind of crank who has so foully shown how barbarous mankind can be.

Because it pays in dollars and cents to be a mouthpiece of discontent and because more money can be made by telling people cheap and tinseled versions of how to offset the inevitable instead of offering honest and manly counsel, we have in our midst a number of foul sheets of sentimentality which are veritable educators to violent and unjust deeds. We believe that our so-termed yellow journals are responsible in large part in keeping alive and introducing into men's minds the seditious principles of anarchy which bear such rotten fruits. We say this advisedly and with a keen appreciation of the psychological principles involved. That public press which distorts and sentimentalizes the smaller details of every-day life is responsible in large part for the mental unbalance of its readers in their judgment concerning the more complicated movements of society. If the facts of every-day life cannot be given to people of minor intelligence in a straightforward and honest manner, is it any wonder that such people fail to see relations as they should be seen and is it incomprehensible that unbalanced social reformers result from such mental training?

Rulers have been killed before printing-presses ever came into existence and they have been murdred for the very reasons that anarchy now preaches as its gospel. Individual leaders have always been found to pander to discontent and human greed. The mantle of the demagogue of old has fallen on the shoulders of the modern sensational press and murder and lust are still fostered beneath its folds.

THE MENTALLY UNBALANCED IN MODERN LIFE.

WITHIN the last three years the world has been aroused to bitterness and startled to the verge of irrational action and opinion by three dastardly attempts upon the lives of rulers. Two of them were unfortunately successful; the third, thanks to the skill of American surgery, now promises to be a happy failure. All three attacks were committed upon individuals whose dispositions were most kindly, whose lives had been free from any stain of personal wrong-doing and whose public careers were not of the character which tends to the making of personal enemies. In the cases of the Empress of Austria and the King of Italy the outrage that caused death was quite as wanton and uncalled for, and the criminals had quite as little personal reason for the attack as in the case of our happily recovering President.

A comparative, even superficial study of the characters of the criminals as disclosed by their history shows certain points of similarity. They

were moody, retiring individuals who made few friends and were largely thrown back upon themselves and their own thoughts during their moments of leisure. All of them seem to have had a craving for the notoriety that their act would bring them and an unfortunate delusion that somehow good would come out of it. Had they been men accustomed to confide in others there would have been some possibility of a correction of their delusion, or, failing that, some warning of the crime to come. None of them had any adequate motive for the crime and yet planned it as carefully and with as much shrewd adaptation of means to the end, as if they were about to perform a praiseworthy act.

In this country this is the third criminal attempt upon a ruler's life. The other two were committed by men whose histories evidently point them out as mentally unbalanced. As a matter of fact such men are not criminals so much as unfortunate human beings led by delusion into the commission of acts that, owing to the instruments of destruction which civilization puts so ready to hand, are much more serious in their consequences than unarmed delusion could effect. Power of evil is placed within reach of the unbalanced and the impulse to exercise it proves attractive to the aberrant fancy and leads on where difficulties would have deterred.

It would seem as though such occurrences must be more or less inevitable in our modern life, for the unbalanced we have always with us and the psychological moment that prepares so sad an occurrence as this may not easily be detected. Yet there are certain lessons that the event teaches, certain warnings that it emphasizes. When the struggle for life was severer than at present many more of the mentally unqualified were eliminated early in life. There is in our crowded world an ever-growing number of individuals to whom chance influences may prove the source of impulses to acts with consequences out of all proportion to the original motives, and it is to be regretted that this country has been chosen as an outlet for an immense number of this class, as well as a general rendezvous for criminals who cannot find a resting place in their own land. There is need, then, for a more thorough and honest control of immigration, and it daily becomes more apparent that not only those who suffer from physical ills and financial stress should be refused an entrance here, but those whose early surroundings and training have been such as to engender the seeds of antisocial conduct. A reconsideration then of the fundamental principles of our immigration laws is therefore a subject of great national concern.

There is, moreover, a further feature in our political system that, taken at its worst, fails most lamentable in the service for which it is created. Meant primarily for the protection of society, our police systems too readily develop a corps of individuals who prey on society, and whose highest ideal at times is expressed not as to the quality of service they can render to the body social, but as to how much they can get out of it. We hold it true that dishonest and corrupt officials, with authority, do much to foster the spirit of discontent and by their leniency in the systematic control of the vicious permit the development of the spirit that seeks to kill.

ECHOES AND NEWS.

NEW YORK.

Once More Dr. Doty and the Mosquitoes.—We learn from the daily press that a change of heart has come over Dr. Doty and that, whereas formerly no means were to be spared for their wholesale extermination, now he is raising them as household pets and further, is reported as being desirous of proving a number of things that are already known. We fear that there is too much press-agent science about this campaign, and would recommend a study of the careful methods now in process of operation by the officers of the Cold Spring Biological Laboratory in their coöperation with the North Side Protective Association on Long Island.

Association of Hospital Superintendents.—The third annual conference of the Association of Hospital Superintendents was begun Wednesday at the Murray Hill Hotel. Charles S. Howell, Superintendent of the West Pennsylvania Hospital of Pittsburg, called the delegates to order. After a brief prayer by the Rev. Dr. Cornelius L. Twing of Brooklyn, Randolph Guggenheimer, President of the Municipal Council, made the visiting superintendents welcome to the city. John W. Keller, Commissioner of Charities, invited the delegates to visit Bellevue and the City Island Hospitals. Various papers on hospital management were read and discussed.

Some Brief Notes Concerning the President's Surgeons at Buffalo.—Many of the practitioners in attendance on the President at Buffalo are well known to our readers. We add here, however, a brief comment on those who were actually engaged in the first emergencies.

Dr. Matthew Mann, who performed the operation for the most part, is well known to the readers of the MEDICAL NEWS. He is fifty-six years of age and is professor of gynecology at the University of Buffalo, and gynecologist at the Buffalo General Hospital, has attained a wide reputation through his standard textbook on gynecology. He is a park commissioner of the City of Buffalo. He has practised from thirty to thirty-five years in Buffalo and has a good reputation as an eminent abdominal surgeon. He was once an instructor at Harvard University.

Dr. Roswell Park needs no introduction. He is a surgeon of world-wide fame and author of "Park's System of Surgery," a standard work. He is also an acknowledged expert in cancer, being vitally interested in the laboratory at Buffalo from which Gaylord's recent researches have come. He is about forty-eight years of age and graduated from the Rush Medical College, of Chicago, some twenty-five years ago and for a time taught there. Subsequently he spent much time in European study and upon his return earned his present reputation as a rapid and clean operator, and is one of the few ambidextrous surgeons in practice. He is chief surgeon at the Buffalo General Hospital and professor of surgery at the University of Buffalo.

Dr. Herman Mynter is an older man, perhaps fifty-six, a Dane by birth and is well known in two continents as an expert abdominal surgeon. Mynter has given the profession an excellent work on appendicitis. Recently he went to Denmark and lectured on his chosen subject before the Danish Medical Congress at Copenhagen. He was formerly surgeon at the Sisters' Hospital and now operates at the German Deaconess Home at the new German Hospital.

Dr. John Parmenter is esteemed as one of the best and most careful of the younger surgeons in the western part of New York State. He is under forty years old and is professor of anatomy at the University of Buffalo.

Dr. Eugene Wasdin, surgeon of the Marine Hospital, Department of the United States, stationed here, will be remembered as one of the experts detailed to investigate yellow fever in Cuba during the recent war. He is about forty years of age and has been a constant contributor to the MEDICAL NEWS on hygiene and bacteriological topics.

Dr. T. W. Lee, of St. Louis, who assisted in the operation, is medical director of the Omaha Exposition and is a well known western surgeon.

Dr. Charles G. Stockton, of Buffalo, was called into consultation because of his store of medical knowledge. He is one of the leading medical practitioners of Buffalo.

Dr. N. W. Wilson, who was in charge of the Emergency Hospital at the time and who was in charge of the President until the surgeons arrived, won a reputation early in his career. He is and has been for three years post surgeon at Fort Porter, is connected with the staff of the Sisters' Hospital and is the sanitary officer of the Pan-American Exposition.

Dr. Presley M. Rixey, the physician to the McKinley family, who is with the President in Buffalo, is a medical inspector in the United States Navy. He is a Virginian, born in Culpeper in that State, and a brother of John Franklin Rixey, the Representative in Congress from the Eighth Virginia district. Dr. Rixey was appointed an assistant surgeon in the regular navy January 28, 1874. His first cruise was in the "Congress," attached to the Eastern station, and when his service on her was completed, in 1876, he was assigned to the Marine Hospital at Philadelphia, remaining there until the following year. His next service was at the Norfolk Navy Yard, and then in 1878 he was assigned to special service. Surgeon-General Bates, of the Navy, who had been Mrs. McKinley's physician in Washington when the President was in Congress and who had resumed that duty when the McKinleys moved into the White House, died in October, 1897. Gen. Leonard Wood, then an assistant surgeon in the army on duty in Washington, succeeded him as the White House physician, and when Gen. Wood went away from Washington as Colonel of the Rough Riders early in 1898, the President chose Dr. Rixey, and for three years he has been constantly in attendance on the President and his wife.

PHILADELPHIA.

Vacancy at University.—The chair of clinical professor of nervous diseases in the department of medicine of the University of Pennsylvania is vacant. Candidates for the position may send notice to the secretary of the Board of Trustees, Rev. Jesse Y. Burk, 400 Chestnut Street, Philadelphia, Pa., before September 28, 1901.

Typhoid Fever.—There is an epidemic of this disease at Bolivar, Penn. Last year hundreds were stricken at the same place. The water supply has been improved since then and at present only twenty cases are reported.

Anthrax.—There is an outbreak of anthrax at Forkville, Penn. Some dozens of cattle are affected and two men, brothers, who skinned one of the fatal cases, are in a serious condition as a result of infection.

Large Bequest to Hospitals.—The will of the late John D. Laukenau after providing for relatives, etc., leaves the residue of the estate to be divided between the German Hospital and the Mary J. Drexel Home. This will give each institution about $600,000. The Society for the Relief of Distressed Germans and the Mt. Airy Orphanage receive $5,000 each. Mr. Laukenau's nurse is bequeathed $2,500.

County Medical Society Divided.—A meeting is to be held at Broad Street and Columbia Avenue September 19th for the purpose of organizing what will be known as the North Branch of the Philadelphia County Medical Society. This step is being taken to increase the attendance at the meetings of the society. Of the 2,500 physicians in the city more than 800 are members of the Society. Only a small percentage of this number attend the meetings, the distance from the homes of a large number being too great. Meetings at two points will obviate this to some extent.

To Consider a New Laboratory.—The County Medical Societies and the State Medical Association of Pennsylvania will consider this month the following resolution: *Resolved,* That we are in favor of the establishment of a Psycho-Physiological Laboratory in the Department of the Interior at Washington for the practical application of physiological psychology to sociological and abnormal or pathological data, especially as found in institutions for the criminal, pauper, and defective classes and in hospitals, and also as may be observed in schools and other institutions.

Damages in Smallpox Cases.—The epidemic of smallpox in Pennsylvania has given rise to two interesting suits for damages. One was instituted by E. C. Myers and his wife against John Crum, a farmer, near Linglestown. Myers' brother while employed by Crum was taken with smallpox. Crum hauled him to Myers' residence, it is alleged, after learning the nature of the disease. As a result Myers, his wife, and their four children were stricken with the disease. While in the pest-house, Myers' old mother, uncared for at home, lost her reason and is now in an insane asylum. The Myers' suit against Crum is for $10,000 damages. The second suit has been brought against the borough of Ashland by Mrs. Elizabeth Burmeister. She claims $10,000 damages for the death of her husband from smallpox. The borough is charged with neglect in not organizing a Board of Health as required by law. The patient, it is claimed, was removed to a pest-house against protest, was uncared for, and was not allowed the services of a physician.

CHICAGO.

Canal Water for Analysis.—Samples of drainage canal water have been taken by Missouri and Illinois experts for analysis, the result to be used as evidence in the great drainage canal case pending before the Supreme Court of the United States between Illinois and Missouri. The samples are to be taken at the same time by both sides and at the same place, and it is expected that from the results reliable evidence will be obtained. In sixteen places along the great waterway from Chicago to St. Louis dippings will be made into the water, each side to analyze its own samples. This result was reached at a recent conference held in the rooms of the Sanitary District between experts from both States. The suggestion originated with Attorney-General Hamlin of this State, who was present with the following officials: Health Commissioner Arthur R. Reynolds, Chicago; Assistant Health Commissioner Reilly, Chicago; Ex-Judge Wm. M. Springer, Counsel of the Sanitary District in the case in the Federal Court; John G. Brennan, Special Counsel for the Sanitary District, and Attorney of the Illinois Central Railway Co., for Illinois, Indiana and Missouri; Dr. Amand Ravold, City Bacteriologist, St. Louis; Dr. Wm. C. Teichmann, City Chemist, St. Louis; and Dr. Adolph Gehrmann, City Bacteriologist, Chicago.

To Rid the State of Quacks.—The Illinois State Board of Health has announced to its attorney that it is about to take active measures for the suppression of quack doctors, dispensaries and medical institutes, whose advertisements enrich the daily papers and attract the ignorant masses. Several individuals have been summoned on the charge of practising medicine without license, and a hearing for the first cases is set for September 9th.

Status of Smallpox in Chicago.—According to the bulletin of the City Health Department, issued August 31st, for the first time in more than thirty months the City Isolation Hospital was empied of smallpox patients last week. Between March 9, 1899, the date of the first case of the series, and August 12, 1901, the date of the last admission, 342 cases of smallpox were discovered in the city, and removed to and treated in the Isolation Hospital. The last case was discharged, cured, August 28th, the resident physician relieved from duty, and the hospital closed. During the period a total of 960,588 persons were examined as to their vaccinal status by the medical inspectors of the Health Department and the public vaccinators, and 220,648 were vaccinated. The greatest number in any one month was 303,725 examined, and 44,904 vaccinated in February, 1901, since which time the disease has steadily declined until the city is now free from the pest. This is a very gratifying contrast to the exhibit made by other large cities of the country.

Improvement in Quality of Milk.—A marked improvement in the quality of the milk supply has followed the posting of the names and addresses of delinquent dealers and shippers, and the confiscation and destruction of adulterated supplies at the receiving stations of the railroad. When this course of action was begun, the proportion of samples tested in the laboratory and found below grade was 22 per cent. During the past four weeks this proportion has been respectively 13.3, 10.5, 10, and last week it was only 6.6 per cent. Some share of the recent great improvement is undoubtedly due to the rains, which have helped pasturage, but that the action of the milk bureau is the impor-

tant factor is shown by the fact that the improvement began before the rains.

Volunteer Medical Inspections.—Dr. John R. Neely, Assistant Chief Medical Inspector of the Department of Health, writing on this subject, states that since these inspections began 10,188 homes have been visited, where lodged 38,966 inmates. There were found 750 cases of sickness, many of which, including cases of contagious diseases, were without medical attendance. The infected homes had not been disinfected, and were foci for the further spread of contagion. The inspection has revealed 5,707 insanitary conditions of all descriptions from unventilated domiciles to the vilest and filthiest of overflowing vaults. These conditions were corrected, largely by the householders, who were impelled to such duty when the danger was made obvious by the earnest and persistent inspector, or more serious defects were corrected through the proper city department. The inspection has been particularly valuable this summer, when so much apprehension existed of the dangers lurking in milk and ice. Especial attention was directed to these articles, and to securing for the people pure and reliable supplies. Investigation by this corps of many deaths from typhoid fever made it possible to locate accurately the cause, to inspire confidence and allay undue fear by suggesting means of prevention. The inspection gives the opportunity to study the home and habits of the poor, what they do for amusement, what they read, what they depend upon to brighten their lives; gives the opportunity to advise exercise for body and mind, to say a word of cheer to the unfortunate, and to listen to the pathetic stories of misfortune and poverty. These inspections are not experiments, they are procedures that pay a heavy dividend in saving life and health. They stimulate a desire for cleanliness that is contagious. They are practical, because they reach the people and bring results.

Dr. Senn on the General Hospital at Samara.—Dr. Nicholas Senn, in an article published in the Chicago *Tribune*, under date of September 1st, writes of this hospital, as follows: "The General Hospital at Samara is located in a handsome park near the western limits of the city, and consists of a number of wooden buildings, in barrack style. Each building does service for seventeen years, when it is removed and replaced by a new one. At present the hospital contains 400 patients. These patients are admitted from all parts of the Samara province and pay 20 kopeks a day. If the applicant is destitute, as is often the case, the district from which he comes pays this small charge for him. We spent half a day in the surgical section, in charge of Dr. Johannes Dsirne, a surgeon of more than a local reputation. We had the pleasure of witnessing two operations for stone in the bladder. Stone in the bladder is quite common in this section of the country, as this surgeon performs annually on an average 100 operations.

"Although the operating-room lacks many of the modern conveniences, the results obtained would compare well with those in our best equipped institutions, something we must attribute to the pedantic cleanliness of the operator and his assistants. The anesthetic, chloroform, was administered by a female feld scheer or barber surgeon, and two other women of the same grade of medical education rendered assistance. The chief assistant was a recent graduate in medicine. These barber surgeons, male and female, are expected to assist licensed physicians, but are not permitted to operate or prescribe except in cases in which the services of a regular graduate in medicine cannot be secured. These barber surgeons must study their profession for four years, and the women are required to take an additional course in gynecology and obstetrics.

"Both patients were puny boys from the steppes of western Russia. In one case the high operation was performed; in the other the stone was removed by median perineal section after crushing.

"It is a fact worthy of note that according to the experience of Dr. Dsirne the peasants are almost immune against shock, he in his large experience having observed only one case. Dr. Dsirne invariably sutures the vesical wound in performing the high operation, using two rows of fine silk sutures, excluding carefully the mucous membrane. In most cases uncomplicated by cystitis he has seen the wound heal by primary intention. If cystitis is present he drains. Dr. Dsirne is a careful, conscientious, and dexterous operator. I am glad to know that he will visit the medical institutions of Chicago some time next summer."

GENERAL.

New Hospital for Newark.—Newark is to have a new Isolation Hospital, to cost $20,000. This was decided upon by the Finance Committee of the Common Council Wednesday night, and the Board of Health was yesterday notified that it might go ahead and build the hospital as rapidly as it saw fit. The city now has only one small frame structure, wretchedly equipped, where over thirty patients have been kept at one time, with but one nurse to care for them. As fast as patients become convalescent they are set to work caring for the others. It will take several months to complete the new hospital.

American Pharmaceutical Association.—The forty-ninth annual meeting of this Association will be held at St. Louis, September 16-21 inclusive. A special rate of a fare and a third has been made by the various railroads for delegates attending the Association meeting in St. Louis. Parties going by way of Buffalo can secure a ten days' stop-over privilege on their return by depositing their tickets with the lo-

cal ticket agent and paying a fee of $1.00. A special party will leave by the Barclay Street ferry, New York City, on Sunday morning at 9 o'clock, September 15th, taking the Lackawanna and Wabash Railroads, and arriving in St. Louis at 2 o'clock on Monday afternoon, one hour before the opening of the first general session of the meeting. The fare from New York to St. Louis is $21.25. In purchasing tickets ask for an Association certificate. On arriving in St. Louis turn this certificate over to Dr. H. M. Whelpley, the local Secretary, who will visé and return it, when a return ticket can be purchased for one-third the outgoing fare. The sleeper fare is $6.00 per berth each way. Parties desiring sleeper reservations should address the undersigned promptly so as to make sure of securing proper accommodations. This route has been selected on account of the beauty of the scenery and the fact that close connection is made and no time need be wasted by men who desire to leave their business for as short a time as possible. All who contemplate going will kindly communicate at once with CASWELL A. MAYO, *Member of Committee on Transport.*

The Contract Doctor in Michigan.—Swedish residents of Ludington, Mich., have introduced there a custom of their country, in the employment of a community doctor. The local physicians, it is said, were banded together for the maintenance of uniform and high charges. This suggested the idea of a health association, which was organized by the heads of 300 families, each of whom pays 50 cents a month towards the salary of a physician whose services are at their command in cases of illness. Many doctors earn no more than the $1,800 a year paid to the Ludington contract physician, but for that sum the organization had to be satisfied with a recent graduate from a medical school, and the probability is that it will always have to be content with a comparatively inexperienced man. The doctor now engaged is satisfied, and he should be. He is gaining experience and has a comfortable salary in addition.

Medical Staff Georgia State Sanitarium.—At a recent meeting of the Board of Trustees of the State Sanitarium (for the insane) in Milledgeville, Ga., July 19, 1901, a commission of physicians, consisting of Dr. W. S. Elkin, Dr. James B. Baird and Dr. J. B. S. Holmes, was appointed to conduct a competitive examination, in Atlanta, Ga., Monday, October 7, 1901, of applicants for appointment on the medical staff of the Sanitarium. This examination, required by the laws of the State, is necessary to render applicants eligible for election to any vacancy that may occur on the medical staff, but does not apply to persons now holding office in the Sanitarium. All applications must be filed with the chairman of the commission, Dr. W. S. Elkin, Atlanta, Ga., at least one day before the time set for the examination. Any member of the commission will cheerfully furnish, upon request, all information relating to the examination that may be desired by any applicant.

New Life Iusurance Tables.—The British actuaries have been preparing a new life table based on their experiences from 1863. Some of their figures are now available. The tables which have been provisionally prepared show conclusively that modern conditions have lengthened the time a man may be expected to live, and they show that fewer people per thousand die annually now than was formerly the case. The data on which this is based have been collected from the records of forty-four English and sixteen Scotch companies. The contributing offices each collected their own data and in addition to the cost of preparing this information they contributed $50,000 toward the expenses of the Joint Committee to which the investigation was intrusted.

The most interesting of the new tables shows how many males healthy at the age of ten years may be expected to live to a green old age. The old table comprised results up to 1863, the new one gives the results between 1863 and 1893, for it has taken eight years to complete these tables. This is the table:

Age.	Old.	New.	Difference in favor of the New Table.
10	100,000	100,000	....
15	98,224	98,284	60
20	96,223	96,453	230
25	93.061	94,387	1,326
30	89,865	91,942	2,077
35	86.281	88,995	2,714
40	82,284	85,467	3,183
45	77,919	81,262	3,343
50	72,726	76,185	3,459
55	66,513	69,919	3,406
60	58,866	62,073	3,207
65	49,297	52,307	3,010
70	38,124	40,615	2,491
75	25,691	27,752	2,061
80	13,930	15,530	1,600
85	5,422	6,350	937

It will be noticed that the new life table shows throughout a lighter mortality than the old one. Another table of importance shows "expectations after the first five years of insurance."

Age.	Old.	New.	Difference in favor of the New Table.
10	100.000	100,000	....
15	98,370	96,943	....
20	96,070	93,893	....
25	91,380	90,810	....
30	86,930	87,632	702
35	81,980	84,258	1,288
40	78,650	80,591	1,941
45	74,170	76,413	2,243
50	68,940	71,482	2,542
55	62,650	65,472	2,822
60	55.160	58,016	2,856
65	45,950	48,811	2,861
70	35,330	37,863	2,533
75	23,720	25,861	2,241
80	12,760	14,471	1,711

Actuaries in this city, commenting upon

these tables have expressed the opinion that their direct effect will not be so much upon the premiums charged as upon the valuations of life offices.

"The new table," one of the actuaries said, "will undoubtedly require smaller reserves at a given rate of interest than the old table did, and the offices will be able to lower the rate of interest assumed at their periodical valuations without actually increasing their reserves to the same extent, as would have been necessary had the old basis been maintained. Those offices, moreover, which keep the rate of interest unchanged will have under the new table a larger surplus to divide among their participating policy holders than would have been brought out under the old table."

Obituary.—Dr. Louis Warfield Ritchie, a physician and life-long resident of Georgetown, D. C., died Tuesday afternoon, at the age of fifty-eight years, from Bright's disease. He was the son of Dr. Joshua Ritchie, a life-long practitioner of Georgetown, and an instructor in Georgetown College. Dr. L. W. Ritchie was in the medical department of the army during the Civil War, and performed notable service at Antietam and other fields.

CORRESPONDENCE.

PARIS LETTER.

(From Our Special Correspondent.)

PARIS, September 1, 1901.

INTRARACHIDIAN INJECTIONS OF COCAINE—LETTER FROM BIER TO RECLUS—ANSWER BY TUFFIER—HEAVY TAXES ON PHYSICIANS IN FRANCE.

THE discussion on intrarachidian injections still goes on. The most recent occurrences are the speech by Laborde, the physiologist, at the Academy of Medicine and the one made by Professor Reclus. The latter caused some comment as Dr. Reclus is the great defender of the use of cocaine in minor surgery and even in such operations as laparotomy and kelotomy, and it seemed surprising that he should have proven an adversary of this new method. In a letter he wrote recently to the *Presse Médicale* he stated that he would gladly adopt it when the mortality consequent on its use was proven to be less than that brought about by the use of chloroform, ether, or the local use of cocaine. Dr. Reclus gave also in full a letter he had received from Bier and from which I shall extract the following statements: "I am glad to find that I hold the same opinions as you, the master in the use of cocaine. As applied in France, the new method can only be denounced as one that should not be tried. It was hardly necessary to perform 1,200 operations to come to this conclusion. I formed my opinion after the first six; I cannot understand the enthusiasm which is not dampened by the accidents that have taken place. I should advise the operators to use the injection on themselves, as I have done, and they might then change their minds. After having tried the method on myself, I abandoned it, but pursued by researches on the subject, and I believe I can now recommend a technic without danger."

Dr. Tuffier, who has been the most determined advocate of intrarachidian cocaine injections in France, considered his method as being attacked and he wrote the following letter to the *Presse Médicale* a few days after the publication of Professor Reclus' letter. He expressed himself in the following manner: "Cocainization, as it has been carried out by Corning and Bier, is a method that is uncertain, blind and dangerous. I should never have dared use it on a human being. I did not find it necessary to gather together 1,300 observations; the first six sufficed, the technic followed out, and the misadventure which happened to one of the authors, whom it was impossible to inject, would have sufficed to calm my enthusiasm and to make me refuse to try it on myself." Dr. Tuffier goes on to say that the same cannot be said of his own technic, which has proved to be sufficiently simple to obtain the favor of his colleagues in all lands, and he has seen both physicians and accoucheurs adopt it. At least a hundred of these injections are made daily, and Dr. Tuffier, taking up Dr. Reclus' words, says that it is this process that he applies with the greatest prudence. If certain surgeons have made rash trials, Dr. Tuffier does not wish to be responsible for their errors or failures, but as for those who have followed out his instructions, he earnestly requests them to publish full statistics for which he declares himself responsible.

Physicians in America are apt to complain of the difficulty of making a living on account of the expenses required by a physician's standing in a community. It may well be asked what most American doctors would think of the heavy taxes which the French medical man is obliged to pay. Every householder in France is obliged to pay a certain tax, but when one has an apartment, one is also obliged to pay a certain percentage of the rent charged. This is the case with most physicians; to cite an example, for a rental of five thousand francs a year or $1,000, one is obliged to pay about 250 to 270 francs ordinary tax. Besides this there is what is called the *patente*, which medical men are obliged to pay like merchants, and this amounts to a matter of 700 to 800 francs, so that a physician is obliged to pay in taxes about one-fifth of this rent. A good deal of complaint has been made about this, and in a recent article published in the *Presse Médicale* the author said that it seemed unjust to impose such heavy taxes on citizens who often enough gave their services for nothing. But amongst doctors there are a certain number who have to pay very heavy taxes. They are the physicians who practise in watering-places. They are requested to pay not only where they have their office, but also where they live the rest of the year. Professor Pozzi and Dr. Pedebidon, who are senators, have been advocating a new regulation, whereby this

category of physicians would be only charged for their office. Another senator, Dr. Labbé, who is well known on account of the gastrotomy he performed some twenty years ago on a man who had swallowed a fork, goes even further and would have physicians taxed only on the rent they pay for their office. It should be remembered that most physicians in France practise where they live, there being very few who have two separate apartments.

TRANSACTIONS OF FOREIGN SOCIETIES.

French.

CANCER OF THE THYROID GLAND—RUPTURE OF THE BLADDER—VESICOVAGINAL FISTULA—CONGENITAL FACIAL PARALYSIS—ANURIA IN PNEUMONIA—HUMAN ACTINOMYCOSIS—ELEPHANTIASIS AND THE EPITROCHLEAR GANGLION—THE RETINA IN ABSENCE OF THE CEREBRUM—STRICTURE OF THE RECTUM—PERSISTENCE OF MECKEL'S DIVERTICULUM WITH FISTULA—LECITHIN AND NUTRITION.

M. Poncet (Lyons), at the Société de Chirurgie, July 24, 1901, read a paper on the subject of cancer of the thyroid gland in which he called attention to the following points. Cancerous degeneration of the thyroid gland is really not a rare affection. True sarcoma of this body is rather uncommon. The forms of cancer usually encountered are of the epithelial type, although the scirrhus has been encountered. Ricard has reported several cases of this which he termed fibrous degeneration after a histological examination. The speaker stated that too much importance must not be attached to purely histological considerations. He felt that in the case of the thyroid gland whenever a hard tumor is encountered, invading the surrounding tissues, vessels, nerves, etc., its malignity should be clinically assumed.

M. Chauvel, in behalf of M. Dubujadoux, narrated the history of a case of rupture of the bladder treated successfully with a retention catheter. The soldier had been subjected to violent abdominal traumatism, which was followed by symptoms of rupture of the bladder. All operative interference was declined. Hence the surgeon contented himself with drainage by means of a retention catheter. The symptoms gradually subsided until finally cure resulted. His suggestion that the rupture was intraperitoneal is undoubtedly erroneous in view of the subsequent course of the case. It must have been purely extraperitoneal.

M. Bazy, in behalf of M. de Spartali (Smyrna) detailed the treatment of a vesicovaginal fistula by the process of infolding. A primary attempt at cure was made after the manner of Doyen. On the fourth day an unaccountable hemorrhage required a removal of the sutures before it could be stopped. Six weeks later he extended a transverse incision through the fistula so as to make two lips which were brought together and folded in upon their deep surfaces. A retention catheter and lateral decubitus for twelve days effected a cure.

M. Marfau, at the Société Médicale des Hôpitaux, July 26, 1901, contributed a few notes on facial paralysis in the newly-born. He stated that this condition has for its usual cause either instrumental traumatism or pressure on the nerves by the bony maternal canal. There are, however, a certain number of cases which depend upon an arrest of nervous development either in the central or in the peripheral portions of the nerve. Such a case he recently had occasion to observe. The child was born with complete right-sided facial paralysis, accompanied by an anatomical malformation of the cavity of the ear. In a few days the child died and the following findings were made at the autopsy. Peripheral degeneration of the nerve trunks, the petrosal bone malformed and consisting of a mere mass without any attempt at the cavities of the middle and internal ear; absence of the intracranial trunk of the nerve and marked atrophy of the nerve centers at the base of the brain. In this case it may be hypothecated that the first thing to be arrested was the petrous bone which was followed by degeneration of the peripheral nerves, then of its centers in the brain.

M. Caussade communicated in the name of M. Gilbert and himself the history of a case of anuria occurring during a pneumonia. The patient, a man twenty-five years of age, developed an almost absolute degree of anuria on the third day of the disease. The amount of urine passed during the next seven days was not over 350 grams. On the eleventh day death supervened. The autopsy showed a marked nephritis. The sections of the kidneys revealed a plugging of all the tubules with casts and red blood-cells. The renal lesion did not seem to have any effect whatever upon the course of the pulmonary. Death occurred with symptoms of uremia.

M. Poncet, at the Société de Biologie, July 27, 1901, discussed actinomycosis as it occurs in the human species. He stated that so far as France is concerned it appears with almost equal frequency in the cities and the country and usually in one of the following locations, the cervicofacial region, the ileo-cecal region and the rectoanal region. Every phlegmon in the neighborhood of the teeth, if very hard and especially if it be somewhat old, should be looked upon as probably actinomycosis, particularly if it is near one of the wisdom teeth and is accompanied by a precocious and persistant trismus. A paraabdominal fistulous tract with neighboring indurations, extensive and simulating cancer, especially in the appendiculo-cecal region and manifestly of intestinal origin, also strongly suggests actinomycosis. Similarly indurated phlegmons about the perineum, without much damage to the urinary functions and evidently originating from the bowel are also likely to be due to the fungus.

M. Tribondeau stated that he had recently had

opportunity among the Pacific Indians of seeing fourteen cases of elephantiasis of the hands and forearms alone and had noticed one singular feature with relation to the epitrochlear glands The process began as a reticulated lymphangitis of the lymph-trunks, usually confined to the ulnar border of the arm and extending upward and suddenly ending at the epitrochlear gland which was usually much engorged, often staphylococci could be obtained from the tissues. The engorged ganglion was at first appreciable only to the touch as a distinct nodule, but soon progressed in size enough to be plainly visible. It then usually continued to grow and finally reached a condition suggesting several superimposed ganglia.

N. VASCHIDE and G. VURPAS, at the Académie des Sciences, July 29, 1901, read a paper on the histological characteristics of the retina in the anencephalous monster recently reported by them. The retina of each side was of normal microscopical arrangement, although the cerebrum was almost totally lacking. The explanation which appears to be the most likely to be true is that the brain developed sufficiently to originate the buds which continue to form the eyes. At this stage the cerebrum ceased to progress and was destoyed by some process similar to inflammation, while the young optic offsets were unfolded to perfection.

M. CHAPUT, at the Société de Chirurgie, July 31, 1901, reported for Souligoux and Lapointe a case of congenital stricture of the rectum which had been complicated with a proliferating and stenosing proctitis. All attempts to dilate from below through the anus had failed. Finally, the stenosis went on to absolute obstruction for the relief of which an artificial anus was made in the left inguinal region. After a while sounds were successfully passed from above downward and a gradual dilation was in this manner carried out until from below it could be maintained. At this time the artificial anus was closed.

M. POTHERAT in the discussion said that the benefit of the artificial anus in itself in these cases was very great, simply by providing a new outlet for the fecal matter. In one of his cases of obstruction due to productive inflammation he found that this forced rest of the bowel brought about a cure without any other therapeutic measures.

M. KIRMISSON reported a rather rare condition in a child. A small congenital tumor had appeared at the umbilicus, rose-colored, about the size of a nut, soft, discharging abundant mucus, and through a sinus in its center admitting a probe for four centimeters. A laparotomy was done and revealed a Meckel's diverticulum. Resection resulted in cure.

M. G. GARRIÈRE, at the Académie des Sciences, July 29, 1901, called attention to the marked effect on growth and development of children incident upon the administration of lecithin. Weight, stature, strength, excretion of urea and carbonic acid gas, formation of red blood-cells and hematoblasts are all increased. These modifications are all apparent from the beginning of the treatment, gradually become less, indicating that the organism has grown accustomed to this substance.

SOCIETY PROCEEDINGS.

AMERICAN NEUROLOGICAL ASSOCIATION.

Twenty-seventh Annual Meeting, Held in Boston, June 19, 20 and 21, 1901.

THE Association was called to order by the President, George L. Walton, M.D., of Boston, in the new building of the Boston Medical Library on The Fenway. In his opening address the President announced the deaths of two members, Dr. Irving D. Rosse of Washington, D.C., and Dr. W. L. Worcester of Hawthorne, Massachusetts. Dr. Worcester's death occurred as the result of a septic wound a few days before the session, and a paper which he had intended to read, entitled "A Case of Cerebral Hemiatrophy with Hemiplegia and Aphasia," appeared in the program for this meeting.

Case of Myeloma of the Spine with Compression of the Cord.—Dr. John Jenks Thomas of Boston read this paper. The following history was given. A man, thirty-nine years of age, was attacked by severe pain between the shoulders which lasted four or five days. After that he improved, but there was more or less pain on movement. Six weeks later it was noticed that there was a slight uncertainty in the use of the legs, some numbness of the legs, and a sensation of constriction about the abdomen. Eight weeks after the onset there was slight diminution of sensation of touch and pain below the eighth rib, and a very slight paresis of the legs without any increase of the reflexes. The spine was freely movable and it was not tender, but there was a slight kyphosis in the upper dorsal region. The symptoms increased and four months after the onset and two months after he was first seen he was confined to the bed with a paraplegia with increased reflexes, loss of the sense of pain and temperature and diminution of the sense of touch to the fourth rib, and paralysis of the sphincters. The spine was not tender and motion was fair. There was a slight swelling on the left fifth rib. The patient was operated on by Dr. Munro and a soft reddish tumor mass was found affecting the lamina and body of the fourth dorsal vertebra and destroying the bone. This was removed as far as possible. The wound healed well and the patient regained completely the strength and sensation of the legs and the control of the bladder. The tumor mass was found to be composed of small round cells with large nuclei, very similar to plasma cells, except for the presence of a nucleolus. There was a very fine reticulum. There was about a quarter of one per cent. of albumose and three-quarters of one per cent. of albumin in the urine, with tube casts. The examination of the blood was negative, except for a leucocy-

tosis of 20,000 without relative change of the varieties of white corpuscles and the normal number of red corpuscles and hemoglobin of 70 per cent. The patient was given bone marrow and Coley's toxins. The operation was done six months ago and there has been no return of the cord symptoms. Tender swellings on other ribs have appeared and quieted down, and about six weeks ago there was a return of pain and tenderness in the back of the tenth dorsal spine, with pain passing about the trunk on pressing on the head.

Myelomata are multiple tumors affecting chiefly the spine, ribs, skull and pelvis, developing from the cells of the marrow, composed of cells resembling plasma cells. They usually produce albumosuria, though this is found in other lymphoid affections of the bones as in pseudoleucemia and leucemia. The most constant symptoms are pains in the back and chest, swellings on the ribs, and deformities of the spine and thorax, sometimes accompanied by compression of the cord. There is no tendency to form matastases, but the disease frequently produces a severe anemia of the secondary type, without megaloblasts in the blood or any marked changes in the number or proportions of the white corpuscles. The interesting features of the case, aside from the rarity of the tumor, are the relief of pressure on the cord by laminectomy, the presence of dissociation of disturbances of sensations, of temperature, pain and touch from pressure upon the cord from without, and the apparent improvement of the condition of the bones from the use of bone marrow and Coley's toxin treatment.

Case of Cervical and Bulbar Tabes with Necropsy.—Dr. William G. Spiller of Philadelphia, with the collaboration of Dr. S. Solis-Cohen, was the author of this paper. In this case syphilis occurred before the onset of the nervous symptoms. There was nocturnal incontinence of urine beginning in 1872 with ptosis of the right upper eyelid in 1879. This could be overcome voluntarily. There was variation in the size of the pupils from time to time; paresis of the facial muscles; difficulty of mastication and deglutition; atrophy of the tongue; disturbance of sensation, especially for temperature and pain; sharp pains in the abdominal region and lower limbs; grayness of the optic nerves and loss of reaction of the irides to light and in accommodation (Edward Jackson, 1888). There was loss of sexual power. The knee-jerks were well preserved. A clinical history of this case was published by Dr. Solis-Cohen in 1889. The symptoms were those of bulbar paralysis; there was general wasting and dissociation of sensation was present. The man worked as a carpenter until within a few weeks of his death. There was no distinct incoordination; station was good. The diagnosis of atypical tabes, made in 1889, was corroborated by the autopsy in 1900 . Degeneration of the posterior roots was distinct in the upper and middle thoracic region and in the spinal root of each fifth nerve. There was integrity of the posterior roots of the lumbar region. Dr. Spiller was of the opinion that the spinal root of the trigeminal nerve would be found degenerated in cervical tabes if it were oftener looked for.

Dr. Joseph Collins and Dr. George W. Jacoby of New York said that they do not find high tabes so very rare. In records of 100 cases of Dr. Collins found five cases of cervical tabes and there was no question of the diagnosis. The poison or toxin of syphilis makes a strong impression on both motor and sensory neurons.

Gunshot Wound of the Spine; Operation; Recovery.—Dr. F. W. Langdon of Cincinnati read this paper. In this case the fifth thoracic vertebra was fractured with penetration of the canal and laceration of the dura. The cord was apparently intact at the operation. Immediately after the accident there was motor and sensory paraplegia with the involvement of the sphincters. The reflexes were abolished, except the plantar which was flexor in direction and sluggish in quality. At the autopsy on the fifth day a central clot in the gray matter was found at the fifth dorsal level; the white matter was fairly preserved in continuity.

Clinical and Pathological Report of a Case of Tabes and Progressive Muscular Atrophy.—Dr. Joseph Collins of New York reported the case of a man with a good early history; gonorrhea but no syphilis; married; one stillborn child. In 1892 he was thrown from a horse, but was not much hurt. He had pneumonia and pleurisy afterward and lost his health. The initial symptom was weakness and numbness of the left hand; atrophy set in; the right hand was also affected. There was no pain. He would drop a pen while at work and was treated for writer's cramp. His bladder was emptied slowly twice daily. Sexual power was weakened. There was numbness in the legs and feet and he could not cross his right knee without assistance. There was wasting below the knee. Pain occurred in the small of the back and was due to weakness of the muscles. There was formication. He was harassed by sudden drawing up of the muscles of the thigh at intervals of about fifteen minutes from 2 a. m. until daylight. There was gluteal atrophy. The treatment consisted of electric baths and strychnine injections. Dr. Collins believes that the type is not unusual; that its primary seat is in the spinal cord and classes the case as one of true progressive muscular atrophy associated with tabes.

Report of a Case of Chronic Hemianesthesia of Over Seven years' Duration from the Destruction of the Carrefour Sensitif.—Dr. Wm. G. Spiller of Philadelphia read this paper prepared by himself and Dr. F. X. Dercum. The patient was a mulatto, who had been under observation for seven years, having right hemiplegia and right homonymous hemianopsia. The symptoms had followed apoplexy, the resulting hemiplegia being slight. There was no impairment of hearing, taste or smell. There was vari-

ation at different times in the extent of the hemianesthesia in the proximal portions of the limbs, but not in the distal portions. There was some spastic rigidity. Dr. Dercum had diagnosticated a lesion of the posterior limb of the internal capsule. Drs. C. K. Mills and G. E. de Schweinitz reported the case in 1869. At that time the patient showed paresis of the right forearm and the fields showed a quadrant hemianopsia. At the autopsy an old cyst was found in the *carrefour sensitif* in the left hemisphere. The thalamus was apparently intact except in so far as it was implicated by secondary degeneration. The motor fibers of the internal capsule were merely slightly implicated. The area affected was studied by several microscopical sections.

Dr. Charles K. Mills gave his opinion regarding the motor and sensory areas of the brain and their boundaries and referred to Schäfer's "Physiology" as presenting these views compactly and thoroughly. He gave credit to the members of the Association for adding to our knowledge of these areas and summoned up the present state of our knowledge under five heads. He instanced the newer observations on the subject of astereognosis and similar phenomena; the studies of the lesions of the superior parietal lobule; facts regarding the *carrefour sensitif* and facts on amyotrophic sclerosis. Mills emphasized the fact that in some of these cases, as in Walton's astereognosis was present without any motor phenomena.

Dr. G. L. Walton believes that we have three sets of sensory areas and that the Rolandic region is not concerned with this. Broca's center is not to be considered in the motor region. The true executive center for speech is at the foot of the Rolandic fissure.

Dr. Mills cited a case of astereognosis without motor paralysis. The autopsy showed in the superior part of the posterior parietal region a large area of disease, not invading the motor zone. He also cited a case of amyotrophic sclerosis. The patient's symptoms were all motor and atrophic. The lesion was pre-central, post-central and in the anterior fourth of the superior parietal convolution.

Dr. F. X. Dercum stated his ground that the sensory fibers occupy a certain position in the internal capsule and are not commingled with any motor fibers, as held by Dejérine. There is no proof that the motor area is in any way an astereognostic center.

Brain Tumor with Unusual Symptoms.—Dr. Wharton Sinkler of Philadelphia reported this case. The tumor was as large as a hen's egg and was attached to the dura over the anterior and posterior Rolandic convolutions. There were no disturbances of pain and temperature sense and only mild motor phenomena. In his case astereognosis was associated with disease of the thalamus.

Dr. C. W. Burr of Philadelphia said that these questions of sensation are the most obscure, judging from the persistent philosophic quarrel on the subject of sensation among men equally well trained. Men, however, are mostly agreed on the function of the cortex. His own opinion is that the motor cortex of the brain is not also a sensory cortex. Along the fissure of Rolando destruction may occur and only motor symptoms appear; back of this is an area which will give only sensory symptoms if destroyed. By our senses we recognize the qualities of an object; intellectual perceptions are in primary centers; these are situated behind the motor area in the Rolandic region.

Dr. H. T. Patrick of Chicago called for more facts clinically and *postmortem*. The only studies of the stereognostic sense are of recent date. He related a case of astereognosis of one hand, without paralysis and with a minimum of sensory disturbance. Hysteria had been diagnosticated in this case. Wherever the lesion is, it does not interfere with motion and very little with common sensation.

Dr. C. L. Dana of New York believes the sensory zone overlaps the motor zone and that the lines have not been sharply drawn. The only question is whether there is an essential identity between motor and sensory centers; or whether the sensory centers are not at all identical with the motor, but posterior to it. He recently had a case in which there was a sarcoma of the left inferior parietal lobe. After removal there was right hemiplegia and very slight paresthesia, but no astereognosis. There was no distinct anesthesia, but a consciousness of disturbance. Loss of muscular sense is due to a lesion of the inferior parietal lobe.

Dr. Mills believes in a strictly limited stereognostic center. He lays great stress on the case of Spiller and Dercum (destruction of the *carrefour sensitif*), a single case studied with the greatest care. He reviewed the older facts supporting separate sensory localization and discussed the bearings on this subject of more recent clinicopathological observations on muscular and cutaneous sensibility and especially on the stereognostic sense, giving his views on the cerebral sensori-motor mechanism.

Acute Multiple Neuritis.—Dr. Charles W. Burr and Dr. D. J. McCarthy of Philadelphia reported the study of a case of multiple neuritis (alcoholic), with incontinence of urine and feces, and death by cardiac failure. The examination of the central and peripheral nervous system revealed besides a parenchymatous degeneration of the vesical nerves, degeneration of the vesical and pelvic plexuses of nerves, of the pneumogastric and phrenic, degeneration of the muscles, selective in character, and perivascular sclerosis in the spinal cord, degeneration extra- and intramedullary of the anterior and posterior roots, widespread chromatolysis of the ganglion cells of the central nervous system and the intervertebral sensory ganglia.

Symmetrical Gangrene.—Dr. C. L. Dana re-

ported the case of a man who had rheumatism in which symmetrical gangrene occurred, affecting his thumbs, hips, toes and shoulder. The gangrenous areas were superficial and painful. The toes broke down, but recovery took place after the use of antirheumatic remedies. Gangrene occurs as a manifestation of many toxic agents.

Dr. Henry J. Stedman of Boston reported a case of symmetrical gangrene of both extremities occurring ten years after syphilis. The endarteritis produced small defects of the skin.

Raynaud's Disease.—Dr. B. Sachs of New York denied that Raynaud's disease is a distinct morbid entity, but is rather a symptom-group. The arterial and venous changes are of prime importance, the nerve changes being secondary. He thought it remarkable that the association of gangrene with general paralysis, as detailed by Stedman, should not be met with oftener.

Dystrophy of the Lower Arm and Hand.—Dr. James J. Putnam of Boston exhibited a remarkable case occurring in a peddler and of five years' duration. He had large shoulder girdle and deltoids and an extraordinary chest with thin muscles. The facial muscles were thin. There was no pain and no assignable cause.

Tumors of the Corpus Callosum.—Dr. Putnam and Dr. E. R. Williams presented a paper on this subject. The first case was that of a woman who had had double optic neuritis; then atrophy of the optic nerve. This was *followed by a second attack of neuritis supervening on the atrophy.* There was great loss of vision with loss of power in the arms and legs with weakness. There were no localizing signs. She died in coma. The second case was that of a man, aged fifty years, who died six months after the first symptoms in January, 1901. In the previous October there was optic neuritis and in November he was operated on by Dr. J. Collins Warren to relieve isolated epileptic attacks. The paralysis in this case was due to pressure. The third case was a male, aged fifty-six years. He was intemperate and died soon after the symptoms began. He had weakness of the left leg and right leg, but not of the right arm. He had delirium and for ten days could not feed himself. The knee-jerk was diminished at first and early disappeared. There was disturbed mental action. Dr. E. Wyllys Taylor reported on the brains. There were no gross signs of degeneration of the cortex or any changes outside of the tumor itself. The term callosal-ataxia fairly described the case.

Four Cases of Brain Tumor with Unusual Symptoms.—Dr. Wharton Sinkler of Philadelphia reported these. The first case was that of a woman, aged thirty years. At thirteen or fourteen she had something like chorea and was decidedly neurotic. She had been married ten years and had two children. For eight or nine years she had trouble with her left arm which gave out after use. Three or four years previously she hit her head on the vertex against a door. In 1899 she had religious melancholia. In June, 1899, she had violent convulsions at night. The condition was considered by her physician to be hysterical. She had a second attack two weeks later. Dr. Sinkler saw her in October, 1900, when she had depressed, psychic symptoms and was hysterical. Her gait was spastic; there was no thermal or tactile anesthesia. The knee-jerk was excessive on the left side. There was no diplopia or hemianopsia. In January, 1901, all the symptoms were exaggerated. There was violent ankle-clonus on the left side, but no facial paralysis and no astereognosis. February 4, 1901, optic neuritis was noted by Dr. A. G. Thomson. Dr. W. G. Taylor operated and found an extremely thick skull and profuse bleeding. A tumor was seen springing from the dura. It was removed and the cavity packed and the bone flap replaced. Saline injections and hypodermics of strychnine were used. The patient recovered sufficiently to answer questions and moved the arm and leg, but died six hours later. The tumor occupied the ascending frontal convolution and was a spindle-cell sarcoma of the size of a hen's egg. The case is remarkable for the latency of the symptoms. Dr. Taylor believes it would be better in a case of this kind to open the skull, pack the wound and remove the growth at a later operation.

The second case was a sarcoma of the occipital lobe. The third case was that of a white man, aged thirty-seven years. The trouble began one year ago with dizziness and pain in the left arm and leg. In March, 1901, there was weakness with incoördination of the left arm and leg, paresis of the left face, violent headaches, dizziness, vomiting, numbness of the hand and twitching of the arms. Station was good. There was no astereognosis. The knee-jerk was exaggerated. Ankle-clonus present. The Babinski reflex was present on both sides. There was choked-disk with diplopia, but no hemianopsia. He died of failure of respiration. At the autopsy a tumor was found at the upper part of the temporal and sphenoidal lobe. There were two growths also at the base. The patient was tuberculous but there was no connection between that disease and the growths in the brain. The one at the base was round and hard as a marble and was the cause of the facial symptoms.

The fourth case was in a man, aged fifty years, who had been in good health and worked as an agent for a drug-house. He was an intelligent, well-educated man. In February, 1901, he was in good health, but his sexual desire had been lost for three years. In April he became indifferent, silent and morose. His physician, Dr. W. D. Robinson, was consulted April 15th and found the man extremely

neurasthenic with symptoms of dementia. He began to practise masturbation and was with difficulty controlled. May 20th he became passive and apathetic. The reflexes were exaggerated. There was slow response to light reflex. He developed bed-sores on the sacrum and died June 2, 1901. There was a growth in the right frontal lobe, involving the corpus callosum and extending over into the left side.

Brain Tumor.—Dr. William M. Leszynsky of New York, and Dr. James H. Glass of Utica reported this case. There had been progressive loss of power in the left arm and hand. There was no headache nor vomiting nor diplopia; no injury and no syphilis. The subject was a man of medium height. His pupils were equal and their reactions were normal. There was slight narrowing of the fields with receding papillitis. There was no aphasia. The dyamometer showed 112 in the right hand and 65 in the left. There was no astereognosis. The patient could not stand. He had talipes equinus. The left knee-jerk was exaggerated. There was no atrophy. A slow-growing cerebral tumor was diagnosticated and an operation was performed in the right Rolandic area. An endothelioma was removed. There was subsequent complete paralysis of the upper left extremity—with muscular rigidity—in the left side. The response to motor impulses was delayed. There were muscular twitchings of the hand and arm with consequent fatigue. He continued to earn his living as an accountant, though permanently hemiplegic.

Dr. Graeme M. Hammond exhibited a plaster cast of a cerebellar tumor.

Traumatic Convulsions. Cranial Operation. An Interesting Pathological Condition. Recovery.—Dr. Frank R. Fry of St. Louis presented the case of a young woman who had received a violent blow on the left forehead when sixteen years of age. Was seen by the writer four years afterward. During all the four years since the accident she had been having hysterical seizures of a typical kind; severe headache, focused at the point of trauma; an increasing mental and physical lassitude. There were no hysterical stigmata of any kind. She had always been perfectly healthy and strong before the accident. The family history was not especially neuropathic. An opening was made in the skull 2½ by 2½ inches. The exposed field of pia-arachnoid showed some slight exudation. When the finger was introduced under the edge of the opening adhesions were found between the dura and pia-arachnoid in every direction. These were broken up with considerable hemorrhage. The wound healed by first intention, the dressing not being disturbed for two weeks. The change after the operation was marked. The patient was *cured*. No headache whatever, no more convulsions. The operation was nearly two years ago and the patient is still perfectly well. The case was compared with a similar one reported by Dr. C. B. Burr, in the proceedings of the American Medico-Psychological Association, 1900. The question of operation in cases of this character was discussed. Useless in hysterical situation to try to formulate any rules for operation except two: (1) If in any case there is doubt about the traumatic origin of hysterical or other psychical symptoms, or of the possibility of surgical relief, the patient should have the benefit of the doubt by an operation. (2) To determine these matters the case should be thoroughly canvassed by a neurologist.

Intracerebral Osteoplaque, with Report of a Case and Exhibition of Specimen.—Dr. Samuel Ayres of Pittsburg exhibited a patient who was an active business man, fifty-four years of age, without specific or traumatic history; having used alcoholic stimulants quite regularly, but not to excess. He had been dyspeptic for many years but had not been troubled with headaches until a month or so previous to his death. His last illness was ushered in by a severe attack of vertigo; soon followed by intense headache in the occipital region. There were no paresthesias or other localizing symptoms whatever. He became delirious and died in coma. The autopsy revealed a large disc of bone adherent to the falx cerebri, from which it was easily separated, compressing the paracentral lobule. This disc, composed of dense bone, was nearly circular in outline, plano-convex, measuring about two and one-half centimeters in diameter, and nearly one centimeter in thickness near the center, from which it shaded off to a narrow edge. The bony plate might have been reached with great difficulty by an operation, but the absence of focal symptoms precluded the possibility of locating the foreign body.

Dr. Sachs remarked upon the surprising adaptability of the brain to pressure from tumors. He cited a case under observation for three and a half years with blindness and dementia for one and a half years. The patient was indifferent to her surroundings and her mental condition was nearly a blank. Now the patient is as bright as previously. There was central scotoma in one field and loss of half vision in the other. After six months there was optic neuritis and then atrophy which has caused permanent blindness. Dr. Sachs believed that operations for the relief of pressure should be encouraged. There was great pain in the branches of the trigeminus and for this a trephine opening was made in one side of the tumor as it presented in the parietal region. The pain was relieved and yet no further attempt could be made to remove the growth. The hemorrhage was great and so the operation was abandoned.

Dr. Mills spoke of tumors of the callosum giving rise to mental symptoms, mental ataxia, etc. He stated positively his opinion

that time was lost by surgeons in these operations. No lectures should be given at the time and no consultations should be held. Surgeons should be more expeditious. There should be no delay in the operation and this not simply to avoid hemorrhage.

Tumor of Cerebellum.—Dr. Joseph Sailer reported this case. The patient was twenty-one years old and had a dizzy headache of the right side. There was a tendency to fall to the left. There was no difficulty in swallowing and no difficulty with the bladder or rectum and no aphasia. The pupils were dilated, with slight lateral nystagmus and slight convergence. There was slight double ptosis; slight optic neuritis. There was double ophthalmoplegia interna. There was no astereognosis nor vomiting. There was gradual loss of memory. There were choriform movements. At the autopsy a tumor was found involving the worm of the cerebellum and measuring 4x3x2.5 cm. It was not very vascular and involved only the posterior portion of the corpora quadrigemina. The anterior portion was not involved.

The Prognosis of Traumatic Hysteria Based upon the After-Histories of a Number of Litigated Cases.—Dr. Pearce Bailey of New York read this paper. He classes hysteria among the delusional insanities. The first case he reported was in a farmer who met with a slight accident after which he became depressed, tearful, apathetic and had a tendency to stagger to the right. At the end of four and one-half years he still has an unsettled claim for damages. The second case was in an actress who had a railroad accident in which she suffered no cuts or bruises. Left hemiplegia and left hemianesthesia ensued. She eventually resumed her vocation. The next case was in a young girl subject to hysteria and chorea. She met with an elevator accident, falling thirty feet; she was not cut nor bruised. Right hemiplegia followed. She recovered $11,500 after which she was married, but walked with a cane. The next case was similar and recovered after receiving a verdict for $4,000. The fifth and sixth cases were accidents from electric shock. The seventh case had lip hemiplegia following hysterical convulsions caused by being thrown from a cart. The hemiplegia switched to the opposite side. He became deaf and dumb. His case was settled out of court, but he was still deaf and dumb one year afterward. The next case occurred March 20, 1900. The man was run into by a trolley car while in a cart. There was a slight injury to the head. He had traumatic hysteria and was seriously incapacitated. He received a verdict for $400 and four months later was at work. Dr. Bailey believes that it is impossible for most of these cases to get well so long as money is at stake, but that is a very different thing from holding that it is the whole cause. The symptoms may last for years and the patients are not always gallery players. Moving the patient from home for treatment is not necessary in all cases.

A Case of Hysterical Paralysis Associated with Black Chromidrosis.—Dr. J. W. Putnam of Buffalo read this paper. Patient, aged nineteen, in good health till eighteen years old, was affected with black chromidrosis for several months. Cheeks and eyelids affected. Later a hysterical paralysis of both legs occurred, which lasted one week. After several months of treatment patient recovered from chromidrosis.

Chorea with Embolism of the Central Artery of the Retina, with Short Review of the Embolic Theory of Chorea.—Dr. H. M. Thomas of Baltimore read this paper. Girl, age sixteen. Family and personal history unimportant. No rheumatism. Seven weeks before admission, right hemi-chorea developed. Sudden blindness in the left eye at about the same time. Ophthalmoscopic examination showed typical picture of embolism of the central retinal artery. Dilated heart with systolic murmur. The ocular complications of chorea. Embolism of the central artery, rare. Seven more or less accurately reported cases in literature. The embolic theory of chorea. Kirkes, Hughlings-Jackson, Broadbent, and others supported it. Dickson and many others opposed it. The seat of the lesion the corpus striatum? cortex? or some other part? No definite data to determine. Suggestions that it is to be looked for somewhere else than in the cortex. Possibly on the afferent side of the mechanism upon which coördination depends. Modern views as to the morbid agent.

Dispensary Treatment of Mental Diseases.—Dr. Walter Channing of Boston read this paper. Insanity requires social as well as medical treatment. For some years the writer has made an effort to help in the solution of the problem of why insanity is increasing and how it can best be treated. Several ways of accomplishing this object. (1) Through discussions in medical and lay societies. (2) Instruction by means of didactic and clinical lectures to students. (3) By the investigation and treatment of patients with more or less mental disturbance in the general community. To accomplish the third object a department of mental disease was established at the Boston Dispensary, December, 1897. Many cases of insanity, both incipient and developed, have been sent to it by the staff and physicians of all the public institutions in Boston. Also cases of neurasthesia, simple depression, alcoholism, defective children, etc. The study of defective children has gradually become an important branch of the work. At present no physicians make a speciality of examining such children. We have, therefore, no system by which a thorough examination can be made and serve as a basis of an expert opinion. The number of defective children in the city is considerable.

Many go unrecognized and later develop into imbeciles, tramps and criminals. The women often become the mothers of illegitimate children. Any means whereby a considerable number of these children can be culled out from the general population and properly treated would be of great public benefit. The work of the Mental Department at the Dispensary has shown the writer that there are more unsuspected cases of insanity of both an acute and chronic nature in the general community than he had supposed. Some incipient cases have been prevented by prompt treatment; others have been cured in a short time either at home or at the hospital. Dangerous cases have been committed. Consultations have been held with members of the staff and patients have been seen with the district physicians at their homes. The opportunity to give instruction to students of the early symptoms of insanity and of the relation of mental to other diseases has been a valuable one, and an important aid to the writer in his course of mental diseases, part of which has been given at the Boston Insane Hospital. Much time has been spent in the examination of each patient which in the crowded clinics of the other departments is less possible. Experience has proved that in the city of Boston there is plenty of material for a mental clinic, and it should be an advantage to the general work of a large dispensary to group cases together for purposes of study and investigation or record, as has been done at the Boston Dispensary.

Dr. Guy Hinsdale of Philadelphia spoke of the successful work of the mental clinic first established in this country at the Pennsylvania Hospital. Mental cases cannot be handled successfully in a general clinic and it is better for the patient to go to a special clinic where physicians can more readily elicit the facts pertaining to this peculiar class of cases. Neurologists can thereby command the advice of alienists in given cases and the admission of such patients to suitable institutions will be facilitated. The medico-legal side of the subject is one of the best reasons for the existence of a mental clinic.

A Case of Fear of Insomnia.—Dr. Edward Cowles of Waverley reported the case of "phobia" existing for years, with resort to devices for seclusion at night and for promoting sleep. Nature of obsessions explained, the imperative idea precisely pointed out, proper substitute suggested, immediate correction of disordered association-process, and recovery. Such primary disorders of physiological mental processes are very common in normal subjects; not necessarily manifestations of constitutional neuropathetic instability. Subjects of acquired or hereditary neurasthenia only more susceptible to influences causing such "dissociations"; insistent and imperative ideas, in various forms, more frequent and striking, but only further modifications or exaggerations in the workings of fundamental elements common to all minds. These affections should not be conceived and classified as essentially neuropathetic.

Two Cases Illustrating the Early Association of Mental Aberration with Syphilitic Infection.—Dr. H. A. Tomlinson of St. Paul recorded the clinical history and *postmortem* findings in two cases of insanity having a comparatively recent history of syphilitic infection, with no apparent involvement of the general nervous system in the one, and marked motor disturbance in the other. The *postmortem* examination in the case of the motor disturbance showed no evidence of gross lesion, while in the other cases without apparent somatic involvement there were a number of gross lesions. The association in these two cases of marked degenerative change in the vegetative organs and their influence on the mental manifestations. The absence or slight development of the ordinary manifestations of syphilis in cases of associated insanity is the experience of the writer.

A Case of Dislocation Forward of the Seventh Cervical Vertebra.—Dr. Frank R. Fry of St. Louis reported the case of a man, thirty-seven years old, who fell from a hammock. Was immediately paralyzed. Examination showed a total paralysis below the seventh cervical segment. The first consultation and serious consideration of the case was twenty hours after the accident. Then a systematic and careful manipulation failed to reveal any injury to the bones. A diagnosis of hematomylea seemed probable, and it was decided to attempt no further examination. One of the consultants took issue, however, insisting that an exploratory incision should be made, especially as an X-ray examination was not available. The patient lived one week. Suffered very little until the last three days. *Postmortem* revealed a forward dislocation of the cervical, its articular facets having just cleared those of the first dorsal. A brief consideration of the special liability of the seventh cervical to this kind of dislocation. The position is taken by the writer that an exploratory incision is the only positive method of diagnosis in similar situations.

Synopsis.—Dr. W. L. Worcester of Hawthorne, Mass., who died a few days previous to the meeting had announced a report of a case of cerebral hemiatrophy with hemiplegia and aphasia, in an adult. Woman, insane at twenty-four years of age, with katatonic symptoms. Recovered, and remained well up to the age of forty-nine, when she had another attack, with similar symptoms to the first. After having been under treatment for this attack for nine months, she had a series of severe convulsions, which left her with right hemiplegia, aphasia, both motor and sensory, and profound dementia. Death, nineteen months later, following another series of convulsions. At

autopsy, no focal lesion found. Great atrophy of left cerebral hemisphere and right hemisphere of cerebellum; moderate descending degeneration of the corresponding pyramidal tract. Appearance very similar to those found in same cases of infantile hemiplegia.

Dr. Edward Wyllys Taylor of Boston presented histories of three clinical cases as follows:

A Case of Poliencephalomyelitis.—Man of twenty-seven, previously well. Influenza in December, 1897. At this time insidious onset of various paralyses, fully developed by March 1, 1898. When examined in December, 1899, the following changes were observed: Paresis of motor portion of right fifth nerve, of all branches of right seventh nerve; paralysis of right external rectus (sixth nerve), paresis of left external rectus; impairment of hearing, especially on right side; paralysis of left recurrent laryngeal nerve; paresis of tongue; marked muscular atrophy of both arms, especially in forearms and hands. R. D. in distribution of cranial and spinal nerves. Insignificant sensory disorders. Improvement under treatment.

The Central Nervous System in a Case of Cancer of the Breast.—Woman of forty-four. Carcinoma of breast; metastases in vertebræ. Much weakness of legs, associated with *absent knee-jerks* and areas of disturbed sensation. Microscopic examination shows marked degenerative changes in ventral horn nerve-cells throughout the cord (Nissl) with secondary ascending degeneration, slight in amount, in the dorsal columns. Motor weakness and absent deep reflexes probably to be explained by alterations in the ventral horn cells, peripheral motor neuroses.

Poliomyelitis of the Adult.—Man of twenty-five, previously well. October 11, 1898, vague feelings of discomfort. Two days later somewhat sudden onset of loss of power in legs, associated with high temperature. Later arms became involved, with some difficulty in respiration. Diagnosis at hospital "Landry's paralysis." Paralysis was flaccid, with absent knee-jerks. Slight improvement in certain symptoms. Death about three months after onset of disease. *Microscopic examination:* Disintegration of ventral horns throughout the cord, extending in less degree to dorsal horns. Abundant evidence of violent inflammation, with extensive destruction of nerve-cells. Marked degeneration of nerve-roots and of sciatic nerve. White matter of cord uninvolved. The confusion of this condition with so-called "Landry's paralysis" is unjustified.

At the business session the following officers were elected for 1902: President, Dr. Joseph Collins of New York; Vice-Presidents, Dr. H. T. Patrick of Chicago and Dr. J. T. Eskridge of Denver; Secretary and Treasurer, Dr. Graeme M. Hammond of New York; Member of Council, Dr. G. L. Walton of Boston.

A note was adopted relative to the death of Dr. Landon Carter Gray, a former president of the Association and its representative to the Executive Committee of the Congress of American Physicians and Surgeons.

The date and place for the meeting of the Association in 1902 are left to the decision of the Council.

BOOK REVIEWS.

The Hygiene of Transmissible Diseases: their Causation, Modes of Dissemination and Methods of Prevention. By A. C. Abbott, M.D., Professor of Hygiene and Bacteriology, University of Pennsylvania. Third Edition. W. B. Saunders & Company. Philadelphia and London.

The fact that Dr. Abbott's book has reached a third edition in the short time since its original publication is a proof of the popularity of the work. The sections, especially on malaria, yellow fever plague, filariasis, dysentery and tuberculosis, have been revised and enlarged. The need for revision and enlargement of so many chapters in so short a time is a good index of the rapid advance in medical science at the present day. Dr. Abbott has succeeded in presenting a large amount of information in a small space. Most of the matter is taken from Dr. Abbott's lectures on Hygiene at the University of Pennsylvania, yet the subject is presented in a very readable way and without obtrusive technicalities. There is about the work in places an air of its having been written for the public rather than for the medical profession. The popularizing of information on hygiene is, however, one of the desiderata of the present generation when newspaper advertisements and other undesirable media are scattering supposed medical knowledge with an evidently interested motive.

International Clinics. A Quarterly of Clinical Lectures and Especially Prepared Articles on Medicine, etc., by Leading Members of the Medical Profession Throughout the World. Edited by Henry W. Cattell, A.M., M.D. Volume II., Eleventh Series. J. B. Lippincott Company, Philadelphia.

The feature of the present volume of the "International Clinics" is Dr. J. F. Schamberg's (Philadelphia) article on "Smallpox, With Particular Reference to the Present Epidemic." This is illustrated by an excellent colored plate of a mild case of smallpox, such as has been most commonly seen during the present epidemic. In this case the grouping of the smallpox lesions on the face, and especially about the lips and nose, was such as to make the affection resemble rather closely febrile herpes. The article is illustrated by five other plates in black and white of typical smallpox eruptions. The differential diagnosis of smallpox is discussed fully, yet briefly, and with the present prevalence of the disease the points

given can scarcely fail to prove helpful to those whose opportunities for the clinical observation of smallpox have been very limited.

There are two clinics on the subject of spinal analgesia. One of these is by Professor Tuffier of Paris, who first employed the method extensively enough to bring it prominently before the medical world. His conclusion as to the method is that whatever may be the field that surgeons shall ultimately assign to analgesia by means of spinal injections of cocaine, it will undoubtedly remain in practice by the side of local and general anesthesia. Professor Tuffier has now employed spinal analgesia in 252 operations, of which 142 were intraperitoneal and 110 extraperitoneal. Perhaps the most striking bit of statistics he gives is that 22 of the cases were private patients.

Dr. Doléris, accoucheur to the Paris hospitals, says that lumbar injections of cocaine have an oxytocic effect and are particularly prone to produce labor. He sums up the result of his observations as follows: (1) The lumbar injection of cocaine is contra-indicated for the execution of any operation during pregnancy, for miscarriage might ensue. (2) A new method of bringing on labor has been found in the use of these injections. (3) This process may render great service in case of uterine inertia during labor, particularly with a moderately contracted pelvis. (4) In eclampsia, when rapid evacuation of the uterus is indicated, the lumbar injection ought to be efficacious and may have a happy effect on the nervous reflex symptoms. This is a new field of usefulness that may prove of practical importance.

ATLAS OF THE NERVOUS SYSTEM. Including an Epitome of the Anatomy, Pathology and Treatment. DR. CHRISTFRIED JAKOB, Head of the Pathologic Institute for Nervous and Mental Disease at the University of Buenos Ayres; Formerly Assistant in the Medical Clinic. Edlangen. Edited by EDWARD D. FISHER, M.D., Professor of Diseases of the Nervous System, University and Bellevue Medical College, New York; etc. W. B. Saunders and Company, Philadelphia and London.

THIS is the authorized translation from the second revised German edition of the well-known German Atlas of the Lehman series of atlases. Dr. Fisher, the American editor, says in the preface that he knows of no work in which so much is compressed within so small a space. The book is comprehensive and practical. The work is certainly calculated to give a very good general idea of recent progress in neurology and brain pathology. The subject is, however, a large one and there are evident signs of the compression that has had to be practised. Somehow an impression remains after looking over the volume that, while it would add very little to the specialist's knowledge, too many details have been crowded into too small a space for it to be very practically instructive for the ordinary practitioner who takes up the book with no knowledge of nervous diseases.

The illustrations, especially those in colors, are beautifully reproduced and the accompanying tracings make excellent guides in brain anatomy and pathology. The illustrations from various cases of special disease of the nervous system are well done as regards plates and text, though it is in this portion especially that there are signs of compression which are almost too noticeable. The volume is an excellent example of good bookmaking at a reasonable price.

PATOLOGIA E CHIRURGIA DEI TRAUMI DEL RIGONFIAMENTO LOMBARE, DEL CONO TERMINALE E DELLA CODA EQUINA. By Prof. D. B. RONCALI. Editrice Dante Alighieri.

THE author of this book, Professor Roncali, is better known in America for his investigations with regard to the etiology of cancer than for work in the surgery of the nervous system. Of late years, however, he has published several books on this subject and in connection with Professor Durante's surgical clinic at the University of Rome has notably illustrated several important subjects. The present volume contains a very good review of our knowledge to date of the physiology, pathology and surgery of the lumbar enlargements, the conus terminalis and the cauda equina of the spinal cord. It is eminently a book for specialists and the indications and contra-indications for laminectomy should prove of practical value now that surgeons no longer consider injuries of the spinal cord beyond their domain. Some of the cases detailed are of great clinical interest because they represent types of unusual traumatic conditions.

MT. SINAI HOSPITAL REPORTS. Vol. II., for 1899 and 1900. Edited for the Medical Board by PAUL F. MUNDÉ, M.D., LL.D.

THE second volume of the Mt. Sinai Hospital Reports is a worthy successor to the first in that it gives a clear account of the excellent work done in that institution and that it enriches medical literature by a series of papers on interesting and exceptional cases. J. Rudisch reports the case of a patient with diabetes mellitus, acromegaly and excessive polyuria, in whom hyperidrosis was a troublesome symptom which persisted despite the administration of agaricine, opium, camphoric acid and petuitary extract; sugar could not be found in the perspiration. The second case is one of diabetes insipidus in which an enormous amount of urine—1010 fluid-ounces—was excreted on one day, and which was completely cured by suggestion; and the third an ambulatory typhoid complicated by bronchopneumonia with delirium and petechial eruption producing a picture resembling typhus.

J. Rudisch and E. A. Aronson in a short statistical article find that diabetes is not altogether a disease of the race, but rather of the class, since far more Germans of the higher class than Russians of the poorer were afflicted, despite the fact that most inmates of the hospitals belonged to the

latter. The relationship of fistula *in ano* to tuberculosis is discussed by Alfred Meyer who finds that 0.87 per cent. of cases of pulmonary tuberculosis observed had a fistula, and *vice versa* 9.3 per cent of fistula cases were consumptive. The frequency of the smegma bacillus in the fistulæ is emphasized and prolonged immersion in absolute alcohol or animal experiment is necessary to determine the presence of the tubercle bacillus. M. Manges insists upon the not too infrequent occurrence of typhoid fever together with pharyngeal diphtheria, despite frequent statements to the contrary, and draws attention to Bouveret's ulcers of the pharynx which he has seen in one case.

"Acute Lobar Pneumonia Followed by Purulent Pericarditis; Pericardotomy; Recovery," is the title of a paper by M. Manges and H. Lilienthal; the conclusions which these authors draw are that in these cases eucaine is the best local anesthetic and that the apparently simple operation of tapping is in reality more dangerous than incision, since the motions of the heart are not unlikely to cause tearing of a coronary vessel by the needle. M. Manges also contributes the notes on a case of exophthalmic goiter with diabetes mellitus and pigmentation and one of rheumatoid arthritis, with exophthalmic goiter in a girl sixteen years old, which are interesting on account of the rarity of the conditions.

N. E. Brill's paper on "Pneumonia and the Acute Hemorrhagic Diathesis" goes to prove that the latter is a rare accompaniment of the former in man, that it occurs more often with the streptococcus than with the pneumococcus and that it is more frequent after the decline of the pneumonia. A most careful bacteriological examination is evident from the article by N. E. Brill and E. Libman on a case of staphylococcemia followed by systemic pyocyaneus infection; it constitutes the first case in which these findings were made in an adult. The same authors also contribute on the subjects of chronic interstitial nephritis and arteritis in the young with a note on calcification in the liver.

Gliosarcoma of the base of the brain is most ably discussed by H. W. Berg, who points out the necessity of determining the side on which these neoplasms are situated by the cerebellar symptoms and the result of the involvement of neighboring structures, before operating. D. H. Davison's article is on the subject of purpura hæmorrhagica.

The report of the surgical and gynecological divisions includes a short account of the subdivision of the work among the staff, the provisions for asepsis and antisepsis in the operating-room, and a review of the many interesting cases and operations during the year. H. Lilienthal relates a case of simultaneous fracture of the vault and base of the skull with recovery and H. Brettauer three cases of primary carcinoma of the vulva.

Three articles written by E. Gruening speak well for the ophthalmic and aural divisions; the first deals with the rarity and the pathological findings of tubercle of the choroid in tuberculous meningitis; the second is instructive for the early recognition of choroidal sarcoma, and the last is a report of two successful operations for otitic brain abscess. C. H. May and C. Koller have also contributed, the former on mastoid operations, the latter on a case of thrombophlebitis of the left sigmoid sinus masking a latent brain abscess which ultimately ended fatally despite operation. These are followed by E. H. Eising's report of anesthesias during 1900 which demonstrates the greater preference for chloroform over ether. Spinal anesthesia apparently has not found much favor among the surgeons, since but three cases are recorded. The interesting volume closes with a paper on the etiology and embryology of dermoid cyst of the mediastinum by F. S. Mandlebaum, with report of a case.

ANATOMICAL ATLAS OF OBSTETRICS WITH SPECIAL REFERENCE TO DIAGNOSIS AND TREATMENT. By OSKAR SCHAEFFER, Privat Docent in Obstetrics and Gynecology in the University of Heidelberg. Authorized Translation from the Second Revised German Edition. Edited by J. CLIFTON EDGAR, A.M., M.D., Professor of Obstetrics and Clinical Midwifery in the Cornell University Medical College. W. B. Saunders & Co., Philadelphia and London.

IN THE preface the editor states that in the original Dr. Schaeffer's "Atlases" were most successful and he sees no reason why they should not be equally popular in the English language and we quite agree with him, since the volume before us will be invaluable for the student, not so much for his first insight into the department of obstetrics, but as a book of reference to be used in conjunction with the larger treatises. The lithographic plates can unhesitatingly be pronounced works of art and the schematic drawings lack nothing in accuracy. For a book whose main features are intended to lie in its illustrations, the text is remarkably full and concise. We are glad to see that that much-neglected subject, obstetrical pathology, receives some credit, though not as much as we would desire.

HOW TO COOK FOR THE SICK AND CONVALESCENT. Arranged for the Physician, Trained Nurse, and Home Use. By HELENA V. SACHSE, Graduate of the Philadelphia Cooking School. J. B. Lippincott Company, Philadelphia.

THIS is a collection of receipts of the best class based on certain dietary principles which are stated in the preface. The opening chapter deals with foods containing no starch or sugar or only a little sugar, and gives a short talk on utensils, weights and measures. Then follow chapters on meat preparations, milk, peptonized foods, drinks toasts, soups, gruels and mushes, eggs, sweetbreads, fish, mushrooms, breads, desserts, etc. There are many palatable dishes for diabetics, and other foods that would be tempting to the invalid's palate. Formulæ for Kumyss, limewater and other sick room necessities are given.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXIX. NEW YORK, SATURDAY, SEPTEMBER 21, 1901. NO. 12.

SPECIAL ARTICLES.

THE CASE OF THE PRESIDENT, CONTINUED.

ON Thursday evening of last week, after the MEDICAL NEWS for the issue of the 14th inst. had gone to press, rumors began to be rife of a change in the President's condition. The symptoms of failing circulation grew urgent and persisted in spite of vigorous stimulation. It soon became evident that a fatal termination of the case, which had seemed so hopeful up to that date, was only a question of time and that the end was not far off. Science could do little more than delay for a few hours the inevitable.

Cause of Death.—The question that interested all citizens and especially the medical profession of this country and, it may well be said, of the world was, What was the cause of the fatal issue? The autopsy was expected to give a clear answer and remove the dark mystery which had baffled the diagnostic skill of the remarkable assembly of medical and surgical experts whose assistance had been sought. The official abstract from the autopsy findings showed very clearly that death was inevitable from the beginning. The wounded internal tissues, instead of reacting so as to produce union, became gangrenous. The declaration in the matter was most explicit. The signed report reads as follows:

"The bullet which struck over the breastbone did not pass through the skin and did little harm.

"The other bullet passed through both walls of the stomach near its lower border. Both holes were found to be perfectly closed by the stitches, but the tissue around each hole had become gangrenous. After passing through the stomach the bullet passed into the back wall of the abdomen, hitting and tearing the upper end of the kidney. This portion of the bullet track was also gangrenous, the gangrene involving the pancreas. The bullet has not yet been found. There was no sign of peritonitis or disease of other organs. The heart walls were very thin.

"There was no evidence of any attempt at repair on the part of Nature and death resulted from the gangrene, which affected the stomach around the bullet wounds, as well as the tissues around the further course of the bullet. Death was unavoidable by any surgical or medical treatment and was the direct result of the bullet wound."

This indicated that death was due to the gangrenous process, but gave very little clue to the cause of the gangrene. Internal tissues injured by bullet wounds do not become gangrenous unless there is some circumstance in addition to the mere passage of a bullet. What this accessory factor could have been has occupied general attention during the week.

Was the Bullet Poisoned?—It was suggested at the autopsy by a well-known medical authority that the bullet was poisoned. Chemical and bacteriological examinations of the cartridges left in the revolver will have to be made to determine definitely this point. In the meantime certain considerations seem to render such an hypothesis unlikely. The poison could scarcely be a chemical irritant, since a 32-caliber bullet could not carry on its outer surface enough of any chemical that is ordinarily known even to medical men to produce such a fulminant death of tissues. As will be remembered scarcely more than one-half the surface of the bullet in a cartridge is exposed for coating with foreign material and any such material would be removed in a great degree during the course of the bullet through the revolver barrel, the clothing and external tissues of the victim. There are popular traditions of virulent poisons that act in minutest quantities, but medicine knows of none that would act as this one is said to have done.

Was the Poison Used a Bacterial Agent and not a Chemical Compound?—this is more possible, but there is no known culture of bacteria that will produce gangrene locally without giving signs of a general septic condition. It has been suggested that if the bullet were dipped previous to insertion in the revolver in putrid meat, gangrene would result wherever it came in contact with the tissues. This would not produce local death of tissue without provoking a reaction. Such a procedure might cause sepsis, but not gangrene, unless the vitality of the parts wounded had been very much reduced. Gangrene is not putrefaction, which is an active biological process due to the presence of living germs, but is death of the tissues involved.

Wound of the Pancreas.—It has been suggested that the President's death was directly due to a wound of the pancreas. The secretion of the pancreas is supposed to have escaped and followed the track of the bullet causing by its presence the gangrene or local death of the tissues wherever it flowed over the wounded part. Against this theory there are a good many objections. The first and most important one is that the track of the bullet seems to have been such that the pancreas was not wounded. The bullet passed through the walls of the stomach near its lower border and so its course would carry it several inches below a normally situated pancreas. Besides this, supposing there was a wound of that organ, pancreatic secretion might

easily have reached the wound in the posterior wall of the stomach, but it is hard to understand how it could have found its way to the anterior gastric wall, since the surgeons declare that the President's stomach was found nearly half-full of food at the time of the operation. A wound of the pancreas, supposing a prolapse of that organ to account for such an accident, would have taken place near its tail where the pancreatic ducts are small and there would be very limited discharge of its secretion.

With regard to the effect of the pancreatic juice, while it produces necrosis of fatty tissue, it does not produce gangrene. The characteristic appearance of the peritoneum where a discharge of pancreatic juice has taken place is well known to those who have seen many autopsies and would have been recognized at once by the experienced pathologists who made the autopsy.

It is true that we are in the dark to a great extent with regard to all the effects of injuries to the pancreas. It is now nearly twenty-five years since Senn, of Chicago, published his work on the surgery of the pancreas of animals, which formed the basis of all medical knowledge on the subject throughout the world, and very little progress has been made in the matter since that time. The surgery of the pancreas was one of the questions for special discussion at the last International Medical Congress and the conclusions reached at that time show how lacking we are in definite knowledge notwithstanding the recent great advances in abdominal surgery.

This much is certain, however, that wounds of the pancreas are by no means necessarily fatal. The escape of pancreatic fluid produces characteristic foci of fat necrosis, but does not produce the lowering of vital resistance which would lead to local death of all tissues with which it happened to come in contact. A number of recoveries from wounds and operations on the pancreas are reported and gangrene is not one of the complications or sequelæ usually anticipated.

Possible Factors in the Result.—There remain certain other organic injuries that may have had their effect in producing the lowered vitality of tissue which led to localized gangrene and consequently to the fatal termination. An extremely important organ, well known in recent years by reason of certain fatalities that have been attributed to it after blows in the region of the stomach, is the solar plexus. The disturbance of the President's pulse during the first few days after the operation was attributed by one of the most prominent surgeons in charge of the case to irritation of this extremely sensitive organ, the abdominal brain as it has been not inaptly called. Unfortunately our knowledge of the functions of the various parts of the nervous system and especially of the abdominal sympathetic nervous system is not sufficient to enable us to say with any degree of assurance what would be the effect of direct injury or serious irritation of this organ. The manipulations necessary for the suturing of the wounds in the stomach had to be carried out in the immediate neighborhood of this delicate organ. This is true, however, in all wounds of the stomach and usually there are no serious consequences. It is not impossible that the irritation produced by the passage of the bullet itself and the subsequent operative procedures should have produced serious sympathetic nervous disturbance. The smaller blood-vessels are especially under the control of the sympathetic. This nervous irritation might have produced the interference with the circulation that led to the local death of tissue. But the direction of the bullet in its course from front to back was away from rather than toward the median lines where it would have involved the solar plexus.

Another consideration that seems worth while discussing is the possible effect of a wound of the suprarenal capsule. The bullet, after its passage through the stomach, tore the upper part of the left kidney and injured the left suprarenal body. A few years ago this would have been considered of no special significance. Now we know that the secretion of the suprarenal capsule is an active agent in producing localized contraction of blood-vessels and consequent diminution of the circulation in tissues. Whether this could have had any effect in lowering the vitality of the wounded tissues and so inducing gangrene is doubtful, but must not be left entirely out of consideration.

There remains the question of the President's individual resistive vitality. There are persons whose reactive power is extremely limited. Diabetics, for instance, are prone to suffer from gangrene after very slight injuries. The late President did not suffer from diabetes, but for some time an abnormal condition of his kidneys has at least been suspected. His age was a factor against his prompt recovery, but should not have made it impossible. Constitutional lack of reactive vitality seems the most important element in the unfortunate and unexpected fatal issue.

It is clear that no human skill could have saved the President's life and that everything that modern scientific medicine could possibly suggest was done for him. The surgeons have been all too freely blamed for their optimistic bulletins. Their wishes may have obscured their better judgments. It is always easy to be wise after the event. At noon on Tuesday, September 9th, the President's pulse was 104 and his temperature below 100° F. This certainly presented a most encouraging condition of affairs after the shock to which the patient had been subjected. There was every reason to think that danger from infection was past. The fatal issue emphasizes the necessity that always exists for most careful prognosis whenever patients are much advanced beyond middle life. The present case, however, contained elements so entirely unusual that no human foresight or even the greatest possible caution could have prevented the sad disappointment that ensued.

ORIGINAL ARTICLES.

DISAPPEARING TUMORS.[1]

BY A. S. WARTHIN, PH.D., M.D.,
AND
W. A. SPITZLEY, A.B., M.D.,
OF ANN ARBOR, MICH.

SCATTERED throughout literature are more or less vague descriptions of tumors supposed to be true neoplasms which, under observation, apparently disappeared and did not recur. In the majority of cases this disappearance was spontaneous or resulted from such slight operative procedures as exploratory incision or puncture. In a few cases it followed operation upon other organs or occurred as the result of a treatment wholly palliative in nature. The tumors described in these cases were not of the nature of "phantom tumors," but were new growths of tissue evident to sight and touch and accessible to surgical examination. If we exclude all of the so-called "phantom" or "apparent" tumors which have been reported under the head of "vanishing" or disappearing" tumors, there is left a fairly large class of cases presenting actual new growths of tissue which under certain conditions either temporarily or permanently disappeared. Occurrences of this nature have most probably come within the experience of nearly every surgeon of large practice, and, while references to such cases are not infrequently met with, no adequate attention has been paid to them.

An analysis of the reported cases of such disappearing tumors shows but few instances in which the pathological nature of the growth was ascertained by microscopical examination, and the clinical data are so confused and unreliable in the majority of cases that they possess but little scientific value. This is true also of some of the cases in which the growth was examined microscopically, the descriptions throwing doubt upon the correctness of the diagnosis. This is especially true of the older cases in which the diagnosis was made at a time when pathological classifications were not based upon such close lines of differential diagnosis as those of to-day. Eliminating such doubtful cases, as well as all cases of phantom tumor, fecal impaction, floating kidney or liver, enlarged liver or spleen, distended urinary and gall-bladder, tuberculous and syphilitic conditions, and also eliminating all cases in which disappearance could possibly be traced to medication (arsenic, cancroin of Adamkiewicz, Coley's toxins, etc.), or in which it could be traced to definite infections, destructive processes of the growth itself, or to intercurrent affections influencing the growth, the reported cases of disappearing tumors fall into three definite classes, viz., benign and malignant neoplasms and inflammatory growths.

Of the benign tumors most frequently undergoing retrograde changes leading to spontaneous disappearance are the different forms of hemangioma and lymphangioma. Power and Johnson have reported cases of the complete disappearance of cystic lymphangiomata of the neck in children. Cavernous and telangiectatic angiomata not infrequently become completely obliterated through thrombosis and subsequent organization of their blood-spaces, the contraction of the newly formed tissue leading ultimately to insignificant scars. Evidences of such spontaneous healing are of frequent occurrence in the cavernous angiomata of the liver. The smaller vascular growths of the skin, pigmented and non-pigmented moles also frequently undergo spontaneous resolution.

Lipomata in rare cases may spontaneously disappear without known cause. Within the past year such a case has come under Spitzley's observation. Thirteen months ago, he saw a boy thirteen years old with a tumor in the right supraclavicular region. The tumor had been of slow growth, having been observed six or seven months before as a small nodule, gradually increasing in size until it was as large as a lemon, though much flattened. It presented all the clinical features of a lipoma, being smooth, soft, painless, situated apparently in subcutaneous tissue and freely movable, without involvement of the skin or deeper structures. At that time operation was advised, but not urged, the possibility but improbability of its spontaneous disappearance being suggested. The parents decided to wait for a time to see whether it would increase to a still greater size. Nothing was heard concerning the case for over a year, when the boy was brought for examination for another trouble; and then in spite of most careful inspection and palpation, no trace of the tumor could be found. It is of interest to note that the boy who, at the time he was first seen was stout, even fat, had during the year lost ten or fifteen pounds in weight.

Nasal polypi may ulcerate and disappear, or through twisting and necrosis of their pedicles remove themselves. Small papillomatous fibromata of the skin not infrequently disappear. Pedunculated fibromata or myofibromata of the uterus may become detached through the tearing or necrosis of their attachments, or, as a result of disturbed blood-supply following such twisting, the entire tumor may become necrotic and be expelled or absorbed. Retrograde changes are of very frequent occurrence in myofibromata; either myxomatous or fatty degeneration, simple necrosis or liquefaction necrosis of the entire tumor may take place, leading to its ultimate complete disappearance. Gibert and A. Martin report many cases of spontaneous regression of uterine fibroid and myofibromata. Chondromata may rarely undergo fatty or myxomatous degeneration and completely disappear. Likewise exostoses may be re-absorbed.

Of the benign epithelial tumors adenomata or glandular hyperplasias of the prostate have disappeared or become smaller after removal of a

[1] Read before the Michigan State Medical Society, Battle Creek May 16, 1901

testicle or section of the vas deferens; fibro-adenomata and cystadenomata of the mammary gland have been similarly affected after ovariotomy. Benign mammary tumors have also disappeared under the influence of pregnancy and lactation. Bryant reports two cases of vanishing mammary cysts. Spitzley has at present under observation a woman forty-seven years of age, who has borne no child for fifteen years, but who on the contrary has shown no sign of climacteric phenomena, in whom during a period of eighteen months there have developed five separate and distinct breast tumors, three in one breast and two in the other. The smaller one was the size of a hazel nut and the larger the size of a butter nut. They were presumably cysts although two of them were so hard that it seemed unlikely that they contained fluid. Unfortunately, through fear, the patient would not allow any kind of surgical interference, not even the introduction of an exploring needle, so that Spitzley is unable to state positively their real nature. The important point, however, is that without medication or manipulation of any kind, each of the tumors disappeared, none of them remaining longer than three months.

Cases of spontaneous resolution of malignant tumors are of much more rare occurrence. The well-known tendency of all rapidly growing malignant tumors to undergo retrograde change rarely reaches a point where it equals or exceeds their proliferative activity. Therefore, while it might be said that all or the majority of the malignant tumors show a tendency to self-limitation of growth through retrogressive metamorphoses, this tendency is but rarely exerted to a practical degree, the peripheral proliferation always surpassing the central death, so that the patient affected dies before the processes of tumor destruction equal or exceed those of proliferation and spread. In a few cases, however, the retrograde processes with subsequent formation of granulation tissue are much more actively manifest, so that actual healing of tumor nodules may take place. Warthin has reported a case of primary polymorphous-cell sarcoma of the nose with universal metastases in which many of the secondaries showed a partial or complete healing, having been replaced by scar tissue. All stages of this process could be traced in different nodules in various portions of the body. The same observer has seen very remarkable evidences of healing in the lung-metastases of a primary sarcoma of the vertebræ. Power, Walsham, and Baker report cases of healing of tumors diagnosed as sarcomata. Baker's case (recurrent tumor of scalp following injury) gave a microscopical appearance of a fibro-sarcoma, and the growth was designated by him as a "withering sarcoma." The tendency of the growths in mycosis fungoides (general sarcomatosis of the skin) to spontaneously disappear forms one of the most striking features of that disease. This disappearance is explained by Orth to be due to a preponderance of cell-decay over cell-growth, the defect thus produced being filled in with scar-tissue. Cases of spontaneous disappearance of carcinomata are more rare than of tumors diagnosed as sarcomata. This is probably due to the fact that some of the tumors regarded as sarcomata were in reality granulation tissue growths; but may also be partly explained by the closer relation of some forms of sarcomata to normal connective tissue and the fact that this is conducive to the formation of scar-tissue.

In connection with this question of retrogressive changes going on in neoplasms, one must, of necessity, take into account those cases in which acute infectious processes supervene, involving the neoplasms themselves and destroying them. Such tumors can not in the true sense be called disappearing tumors any more properly than can those subjected to the action of the mixed toxins. M. Richardson, before the American Surgical Association in 1898 reported a case of destruction of a round-celled sarcoma by wound infection; and recently a case has been reported in which infection supervened in the wound of an operation attempted for the clearing out of a carcinomatous axilla (secondary to mammary carcinoma), but abandoned because of the extraordinary involvement of all tissues, and three and a half years later showed no evidence of remaining malignant disease, the infection having presumably destroyed all involved tissues. As mentioned above, however, such cases should not be considered in the light of disappearing tumors, but as shining examples of accident pointing the way to successful therapeusis.

Kaposi has reported instances of spontaneous cure of epitheliomata of the skin. Stoerck reports an epithelioma of the tonsil disappearing without interference, but recurring within a year. Senger claims to have seen certain tumors of the buccal mucous membrane having the microscopical appearance of carcinomata disappear after the removal of jagged and irritating teeth. Doubt upon the carcinomatous nature of these growths has, however, been raised. Freeman describes a case of apparent disappearance of epithelioma of the lip, with fatal development of secondaries in the submaxillary region two years later. Billroth and many others report instances, particularly in old women, of the spontaneous disappearance or decrease in size of scirrhous cancers of the mammæ. Recently Osler has reported two cases of spontaneous disappearance of secondary growths arising from primary mammary cancers. He quotes similar cases of Vulpian and Gould. Since the use of erysipelas toxins in the treatment of inoperable neoplasms a number of cases are reported in which great reduction in size followed injection of these toxins into the new growth. No well authenticated case of complete cure by such treatment has been reported, and it is probable that the only effect of such treatment is to cause a more rapid retrograde process whereby the size of the tumor becomes rapidly reduced.

Into the third class of disappearing tumors falls a large class of new-formations of tissue which

are not of the nature of neoplasms. They are found chiefly in the peritoneal cavity, omentum or retroperitoneal region. Though in many instances mistaken both on physical and surgical examination, and in a few instances on microscopical examination, for sarcomata, they are in all cases to be regarded as of inflammatory origin. They arise in almost every instance from a local peritonitis, whatever its cause, but are most frequently found in association with appendicitis and salpingitis. The physical characteristics of these tumors vary greatly. They may form large, small, round, nodular, flattened, movable, immovable, sensitive, or painless masses presenting in any portion of the abdomen or pelvis. The greater portion of these tumors is usually formed by the omentum which almost immediately attaches itself to the inflamed area. Granulation tissue is rapidly formed in large amounts and a tumor mass is formed which may be acute, disappearing ultimately; or chronic, forming a thickened mass of scar tissue which may or may not be adherent to other portions of the peritoneum. Such tumors may occasionally reach a large size from extensive formation of granulation tissue or from the presence of pus-cavities. Similar formations of granulation-tissue may be found retroperitoneally in cases of pancreatic or renal disease, and also in association with appendicitis. In the great majority of cases the omental tumor follows appendicitis or salpingitis. In this connection should be mentioned a class of tumors of great importance but to which little attention has been given. Chronic inflammatory swellings of the head of the pancreas in association with cholelithiasis are not of infrequent occurrence. A number of these cases have been reported in which there was such enlargement of the head of the pancreas found in operating for gall-stones that the condition was diagnosed as primary cancer of this organ, but total disappearance of the tumors took place within a year or two after the removal of the gallstones. This condition has been variously interpreted, but no adequate explanation has as yet been reached. It may exist without involvement of the common duct through obstruction by gall-stones.

Summing up the reported cases of the disappearance of tumors consisting of actual new growth of tissue, we find that such event is of too rare occurrence to justify delay in operative procedures. While a few benign tumors may spontaneously heal, even in these cases there are inconveniences, and in case of necrosis, actual dangers in permitting this process to take place. In the case of malignant tumors the instances of complete disappearance are so rare and in the majority of cases so doubtful that this event is to be regarded in the light of an interesting pathological phenomenon without practical clinical value. Only in the third class of disappearing tumors, the inflammatory growths, may operative measures be delayed or dispensed with entirely with reference to the possibility of spontaneous cure. In all cases, however, the microscopical nature of the growth should be ascertained when possible. Further, it is practically only in the case of abdominal and pelvic growths that growths of this nature are to be looked for. The following cases are most interesting examples of disappearing tumors of this class, and are of additional value for the reason that microscopical examination was made of the tumor in two of the cases, thereby affording satisfactory explanation of this clinical course. The first three came under our observation in the surgical clinic service of Dr. Nancrede of the University Hospital.

Case I.—Mr. L. A., aged twenty-eight years, Danish farmer, was admitted to the surgical clinic of the University Hospital, January 23, 1899. He gave a clear history of an attack of acute appendicitis occurring six weeks previously. On admission to the hospital, there was no evidence of any continuation of the acute condition either locally or generally. There was, however, a distinct tumor, very hard and without pain or tenderness, palpable in the right iliac region and for this condition on April 10, 1899, exploration was undertaken. The tumor mass was found to be intimately connected with the tissues of the anterior abdominal wall. There were softened areas in it but no real pus. The mass was believed to be a neoplasm; the softened parts were curetted, but because of the involvement of the appendix, omentum, caput coli, anterior and lateral abdominal walls, no attempt was made to remove the appendix. Tube drainage was instituted and the wound was closed in the usual way; there was never any evidence of suppuration.

When the patient was discharged seemingly all trace of the tumor had disappeared. According to a report from the patient a few months ago, he has remained well so far as his appendiceal region is concerned.

Pathological Report.—Small portion of tissue sent for examination. Fixed in bichloride and embedded in paraffin. The sections first examined showed a structure composed almost entirely of thin-walled blood-vessels surrounded by a mass of round spindle cells lying in a scanty reticulum. The resemblance to an endothelioma was so great that a preliminary diagnosis of this nature was sent in. Further study with different staining methods showed that the tissue was of the nature of granulation tissue and not malignant. Such diagnosis was therefore sent to the surgeons a few days after the first one. The diagnosis of granulation tissue was based upon the presence of numerous plasma and mast-cells, the rarity of mitoses, and the presence in areas of small vessels having greatly thickened walls and hypertrophic endothelium as in chronic granulation tissue. Staining for micro-organsms negative. Diagnosis, granulation tissue, probably resulting from appendicitis.

Case II.—Mrs. C. S., aged 40 years, was admitted to the University Hospital, March 4, 1899. She complained of intense abdominal pain. Her history showed that she had had an attack of peritonitis when she was sixteen. In November,

1898, and in January, 1899, she had attacks of severe abdominal pain lasting several days. This pain was accompanied by marked febrile symptoms; there was present also during the most recent attack, a tumor in the right iliac region, which disappeared synchronously with the fever.

When admitted to the hospital she had been ill for a week or two; she had considerable abdominal pain, beside many signs and symptoms of an infectious process. There was also slight tumefaction in the right iliac region and about the umbilicus. She was operated upon on March 6, 1899. The incision was made in the right linea semilunaris; a mass was found which involved omentum, small intestines, colon and anterior abdominal wall and which contained many enlarged lymph-glands. No macroscopic pus was present. The appendix, together with part of the attached omentum was removed, the wound drained and closed. She made an uneventful recovery and is now well.

Pathological Report.—The fresh specimen consisted of a flattened nodular mass about the size of a man's fist. On section it was extremely vascular, resembling granulation tissue. Small areas of fat tissue were visible on the cut surface. The material was fixed in bichloride of mercury and embedded in paraffin. The microscopical sections showed the mass to consist of the inflamed omentum with extensive formation of granulation tissue about the blood-vessels and upon its surface. Large areas of small-celled infiltration were present, in some places amounting to purulent collections. In these large numbers of cocci and bacilli were present. Diagnosis, subacute inflammation of omentum following rupture of appendix.

Case III.—Mr. A. J. W., aged fifty-two years, came to the University Hospital on April 17, 1899, because of a large abdominal tumor. He had first noticed the tumor in December, 1898, at which time there was considerable pain and tenderness present and since which time, he had had five distinct attacks of pain occurring in the region of the tumor. He had lost considerable in weight and was cachectic in appearance; at no time while under our observation was fever present. Exploration was undertaken on April 24, 1899. The incision extended from the ensiform cartilage to below the umbilicus and was made in the linea alba. The incision revealed an immense tumor involving the stomach, the sigmoid flexure, the regions posterior to the stomach and colon, the descending colon, and the transverse colon. The tumor was very hard, the neighboring lymph-nodes were much enlarged; there was no suppuration and the tumor did not apear like an inflammatory mass. It was impossible to remove the mass; after irrigating the abdominal cavity with normal saline solution, the wound was closed. The patient made an uneventful recovery from the operation and was discharged in four or five weeks. In August, 1899, the patient reported that he had gained forty pounds in weight and was in perfect health. Three months ago, he reported that he continued to be well and that all trace of the tumor had disappeared.

Unfortunately, no part of the tumor was removed for microscopical diagnosis. It was believed to be malignant and was inoperable. During his convalescence and afterward, naturally the question of a possible tuberculous condition came into mind, but, from observation of the case, it is impossible to conceive it to have been such.

In addition to the above, five other cases have come to our notice in which seemingly malignant growths, or at least seeming neoplasms, have curiously disappeared; three of them occurred in the practice of Dr. J. H. Carstens of Detroit, and two in the practice of Dr. Donald McLean of Detroit. We shall not report them in detail, but merely state that of the first three one was a case in which gastro-enterostomy was performed for relief of a rapidly growing pyloric tumor, believed to be sarcoma. Not only was there relief from the symptoms of obstruction, but there was was marked decrease in size, in fact disappearance of the tumor. At the end of two years the patient died; no autopsy was obtained.

Another was a case in which exploratory incision revealed a great number of small abdominal tumors involving all the viscera. They were thought to be multiple sarcomata. At the end of three years the patient is well.

The third case is one in which all the viscera were involved in one large mass. There were symptoms of pyloric stenosis; the tumor was thought to be carcinamatous and was inoperable. At this time, two years since exploration, the patient is well and the mass has disappeared.

Of Dr. McLean's two cases, one was a patient in whom he was induced to make an exploratory incision, although the large abdominal tumor present was believed to be and was found to be inoperable. Three months later, he had occasion to see the patient and careful examination failed to reveal a trace of the mass remaining.

The other patient was a woman, sixty years of age, who had a very large abdominal tumor. She was confined to her bed because of its size and weight. Nothing was done to relieve her condition, it being believed that death must soon ensue. He had her under observation for four or five years during which time the tumor gradually decreased in size, until it had completely disappeared. The patient lived to be more than eighty years old.

In conclusion, we wish to emphasize a few points which are of some clinical importance:

First, that in spite of skilful clinical observation, the ultimate behavior of a tumor is seldom to be determined except by microscopical examination, and that many seeming malignant neoplasms are taken to be such when really they are but the outcome of an inflammatory condition.

Second, that probably no true neoplasm, malignant in nature, ever disappeared except through retrograde changes induced into itself through in-

fection of the tumor tissue, or through affections or infections of other parts of the body having, by reason of toxins, practically the same effect. To this there are extremely rare exceptions in which the disappearance of the growth takes place by an excess of retrograde processes over those of growth.

Third, that we must look to the inflammatory process, acute or chronic, for the explanation of the appearance and disappearance of these masses of tissue which before and even during exploration appear to be actual new growths.

THE DILATATION OF THE CERVIX UTERI IN OBSTETRIC PRACTICE.[1]

BY HENRY J. GARRIGUES, A.M., M.D.,

OF NEW YORK;

CONSULTING OBSTETRIC SURGEON TO THE MATERNITY HOSPITAL; VISITING GYNECOLOGIST TO ST. MARK'S HOSPITAL; HONORARY FELLOW OF THE AMERICAN GYNECOLOGICAL SOCIETY, ETC.

CÆSARIAN section and symphysiotomy make a great impression on the lay mind and probably to a considerable extent on that of the general practitioner, but we who have performed all obstetric operations know that in reality these two are very simple. To do a forceps operation well is often much more difficult and requires more skill than either, and version and extraction are the acme of obstetric art. Still the number of those who feel competent to perform Cæsarian section or symphysiotomy, and who can command the necessary assistance, is small and chiefly limited to those who are connected with a lying-in hospital, while almost every practitioner of medicine, especially those living in the country or in small towns, is forced to use the forceps and perform version.

The forceps should never be applied before the os is completely dilated, and the same rule holds good in regard to version, if it is to be followed by immediate extraction. The consideration of the means at our command for inducing, increasing and completing the dilatation of the cervix comes therefore as a proper introduction to the discussion of forceps delivery and version. But unfortunately the time accorded each reader of a paper this evening is so short that I can not do more than skim the subject.

During pregnancy dilatation of the cervix is especially needed in abortion cases, artificial abortion, and induction of premature labor. The first two can hardly be called deliveries, and are therefore outside of the scope of the present disquisition.

Labor may be induced in many ways, but some of them have proved vastly superior to others in regard to efficiency, safety, and expeditiousness. While the obstetrician always can perform artificial abortion, it is not so with induction of premature labor. Here the collaboration of Nature is an absolute requisite and must be solicited. We can do much to help Nature, but the one thing we must await from her side is the contraction of the muscular wall of the uterus—without uterine contraction, no labor. In most cases of this kind there is no hurry, and then it is well to use repeated vaginal douches with hot water or alternately hot and cold water. This may be combined with the tamponade of the vagina. Both these methods have, however, the drawback that they impair the epithelium of the vagina, and they may be dispensed with, if a bougie can be introduced into the cavity of the uterus. For this purpose we choose an English bougie No. 10, the French being too flexible. First the bougie is disinfected by immersion for ten minutes in a solution of bichloride of mercury (1-1,000) and lubricated with boiled glycerin, with or without the addition of corrosive sublimate (1-1,000). It is introduced without a stylet, which would make it too stiff. The patient is placed in Sims' position, a Sims speculum is introduced, the cervix is seized with bullet forceps, and the bougie is inserted in one of the sides of the uterus, in order to avoid the placenta, which generally is attached to the anterior or posterior wall. It should be pushed in to its full length except the last two or three inches, which are bent in a circle at the vault of the vagina and held in position with a pledget of iodoform gauze.

When the cervical canal is sufficiently dilated to admit a finger, then the bougie may be removed and Robert Barnes' dilators used instead. The action of the cervical bags may be intensified by placing a colpeurynter in the vagina. If labor pains are not brought on, Champetier de Ribes' large, pear-shaped, inelastic bag may be introduced into the uterine cavity and left till it is pushed out by uterine contraction, or this action may be combined with a downward pull either by the hand or by a weight.

If the bougie and dilators have not brought on labor pains, or at least not sufficiently strong ones, the bag of waters may be ruptured.

Some years ago the injection of glycerin into the cavity of the uterus was recommended, but in some cases it gave rise to hemoglobinuria and chills, and therefore this method should not be used. Finally, the constant electric current may be applied at intervals, like labor pains.

During labor it is, especially in cases of placenta prævia or eclampsia or in threatened death of the fetus, that dilatation of the cervix is called for, and in these cases it is desirable to obtain full dilatation in the shortest possible time. In other cases in which the os opens imperfectly, the cause is nearly always a mechanical disproportion in the size of the fetus and the parturient canal.

I shall now briefly review the means we have of dilating the cervix during labor.

Certain drugs are of more or less value in this respect and may be used where there is no imminent danger or may be combined with the mechanical resources we presently shall enumerate. From olden times belladonna has been used. To smear the unguentum belladonnæ on the cervix must be looked upon as obselete on account of the

[1] Read as part of a symposium on "Means of Artificial Delivery" before the Obstetric Section of the Academy of Medicine.

danger of infection, but in the refined shape of atropine dissolved in sterilized water it may be injected into the tissue of the cervix in the dose of $^1/_{40}$ grain.[1]

The cervical portion may be painted inside and outside with a 10 per cent. solution of cocaine.[2] Chloral hydrate, gr. xv. every twenty minutes for three or four doses, is excellent. Antipyrine, gr. x every half hour, three doses if necessary, has undoubtedly great oxytoxic value, and so has strychnine, gr. $^1/_{30}$, repeated every twenty minutes until gr. $^1/_{10}$ has been given. Quinine in 10-grain doses has also been praised. Ipecacuanha, gr. ij to v, repeated every twenty to thirty minutes, is disagreeble inasmuch as it nauseates the patient, but it conquers rigidity of the cervix.[3]

Among the mechanical means of dilating the cervix I shall first mention tamponade. This may be applied to the vagina, the cervix or the interior of the body of the uterus. A good way is to insert a strip of iodoform gauze into the cervical canal as far as it will go and pack the vagina with the same material or cotton wrung out of creolin (1 per cent.). The next day the packing is removed, and then the internal os will probably be found sufficiently dilated that new gauze may be placed beyond it, inside of the lower uterine segment, where it works as an irritant calling forth uterine contractions.

If the situation is such that we want the os dilated as rapidly as possible, for instance, in a case of uterine hemorrhage, we have different resources, namely, manual dilatation, dilatable bags filled with fluid, expanding metal dilators, and deep cervical incisions.

Manual dilatation is of great value. Those who have not tried it, have no idea how often the cervix toward the end of pregnancy may be so dilatable that in fifteen or twenty minutes it may be fully dilated. Manual dilatation as exercised nowadays differs much from what was known a few years ago. Until then it was really an *accouchement forcé*. We introduced first one finger, then two, three, four, then the whole hand, formed into a cone, always pressing upward with counterpressure on the fundus. In 1894 Dr. Philander A. Harris[4] of Paterson, N. J., taught us his method of dilatation by which the cervix is opened by pressure with the index finger and then dilated by lateral pressure exercised with the crossed thumb and fingers, using the flexor muscles. I regret that time does not allow me to say more about this method than that it has given entire satisfaction in my hands.

The other modern method is that of Bonnaire of Paris (1897). The first step is the same as in Harris' method. When the cervix is closed, the right index-finger is pressed through the whole cervical canal. It is then used to massage the surrounding tissue in an eccentric direction, until the index-finger of the other hand can be brought in, back to back with the first. These two now exercise lateral pressure until a third finger can be introduced, and so forth, until the three longest fingers of each hand are inserted, by means of which the cervix is fully dilated.

Either of these methods is preferable to the old pressure with the cone-shaped hand, which is apt to cause great tears, and it is preferable to any hard dilating instruments. Having the fingers directly in contact with the tissue we press on, we can better judge of its condition, and treat it with greater gentleness.

Bags capable of being filled with fluid are also of the greatest value. We have two classes of apparatus, the elastic and the unyielding. The elastic bag was first used in the vagina as Braun's colpeurynter, then in the cervix as Robert Barnes' fiddle-shaped bags, and, finally, in the uterus above the cervix—Tarnier's balloon.

Braun's colpeurynter acts slowly by inducing uterine reflex action. Tarnier's intra-uterine bag obtains the same by action directly on the lower uterine segment. Barnes' cervical dilators add to this irritation direct expansion of the cervix. They are most excellent as far as they go, but the largest dilatation obtained by them is only seven inches in circumference, or about two and one-quarter inches in diameter.

It was therefore a decided progress when Champetier de Ribes in 1888 invented his pear-shaped, unyielding bag, which when fully dilated measures nearly four inches across the base. German obstetricians (Mäurer, Arthur Müller and others) have made the bag much stronger and applied a new principle to it by attaching a rope to the tube of the bag, leading it over a pulley, and hanging weights weighing from one to three kilograms at the other end of the rope.

But in spite of indisputable merits these instruments are not without drawbacks. They are apt to provoke too rapid and violent labor pains, they favor the prolapse of the umbilical cord, and they may push the presenting part away from the brim of the pelvis. It is also a drawback that special, somewhat expensive and heavy forceps are needed for their insertion. The bag is particularly praised for induction of premature labor, which it accomplishes in much shorter time than does the bougie treatment.*

It is also of the greatest value in cases of placenta prævia, the treatment of which it has changed. Instead of turning by Braxton Hicks' method and using the thigh and breech of the fetus as tampon, the large unyielding bag, introduced through the torn membranes or perforated placenta, arrests the hemorrhage and allows the use of the forceps, which in Pinard's service has reduced the maternal mortality to 2.6 per cent. and the infantile to 6.8 per cent.[5]

The hard dilators can also be divided into two classes—those with which pressure is exerted all over the circumference, but chiefly in the direction of the longitudinal axis of the cervical canal, and those which exercise only lateral pressure, but then necessarily only on comparatively small parts

* Rubeska, of Prague, Centralbl. f. Gynäkologie, Vol. XXIV., p. 1138, reports an average of thirty-five hours compared with fifty-five hours.

of the cervix at a time. The first class of instruments is either cone-shaped or olive-shaped—Hanks' coniform dilators, which are a modification of Hegar's, his large olive-shaped dilators, and my own olive-shaped dilators, which fill the gap between the two. These instruments are all appropriate in abortion cases. In delivery at or near term, the other class is preferable. There is a variety of hard dilators with a number of branches varying from two to four—Arthur Müller's, Starlinger's and Gau's have two, Tarnier's and Bossi's three, Schwarzenbach's four.[6] They differ also much in the shape of the distal end. Starlinger's has a very thin part near the end, which evidently is meant for entering a narrow cervix, but makes the instrument too dangerous. Tarnier's, Bossi's, Arthur Müller's and Gau's have the distal end flattened and bent outward so as to prevent the instruments from slipping. I think Bossi's instrument (1890) is most used, and the reports about its efficacy are quite favorable. In severe labor cases the cervix can be opened in from fifteen to twenty minutes[7] and in abortion cases sufficient dilatation is obtained in five or six minutes.

To instruments applies the same that I have said about manual dilatation. Lateral pressure, even if it is exercised only on a few points of the circumference at a time, is to be preferred to the pushing upward of large bodies in the direction of the cervical canal. By moving the rods of the expanding dilators around to different parts of the cervix we obtain an even dilatation and are less apt to tear the cervix and the parametria.

Finally, we have the method of cervical incisions. To make multiple small incisions in the circumference of the os is an old method that often has proved useful in overcoming rigidity of the cervix, but sometimes the incisions tear out.

Deep incisions, 2, 3 or 4 in number and dividing the whole vaginal portion out to the vault of the vagina, are perhaps also an old method[8] but the procedure has become more generally known through Dührssen of Berlin. In order to obtain the full intended length of the incisions, it is necessary to seize the cervix with two pairs of bullet forceps and cut between them.

The advantage of the method is that it affords space immediately, but it is only indicated when the cervix is obliterated and the os not sufficiently dilated. There may also come hemorrhage after delivery when the pressure exercised by the presenting part ceases; the danger of infection is increased, the incisions may not heal together, and in spite of their length, they may tear and extend into the perametrium. If these incisions are made at all, it is better to close them with sutures immediately after delivery, by which hemorrhage is arrested and linear union without cicatricial tissue is obtained. But this is in itself not easy. I think this method can hardly be recommended when compared with bloodless dilatation with hands or instruments. The deep incisions may save a child's life, but it exposes the mother to immediate danger and remote suffering.

THE PANTHERAPIST AND NEOTHERAPEUTICS.

BY C. H. KERMOTT, M.D.,

OF FORT TOTTEN, N. D.

WE ARE living in an age of expansion and rapid progression. Expansion generally follows united efforts. By the union of States the United States of America has become the greatest nation upon the face of the globe. By the union of nations every separate nation is compelled to respect its own people and to punish them, when it is deserved by them.

A union of the different classes of therapists which we have in the State of North Dakota, would bring about a much more satisfactory condition of affairs than that which exists at present.

We do not doubt that all classes of physicians in this State are doing the best they can, and that there is perfect honesty in their intents. Each class, so far, is trying to run in the particular groove in which it has been educated. When these classes met with those not of their ideas there is frequently a clash, and, as in a hurdle race, each tries to throw obstacles in the way of the other; invariably one, but generally both are injured.

The Pantherapist.—The Pantherapists ($\pi\alpha\nu$, all, and $\theta\varepsilon\rho\alpha\pi\varepsilon\upsilon\omega$ I care for), as the name implies, are those who in their care for all are ready and anxious to draw their information from any and every source that is conducive to lessen the cause of disease, restore the health of the afflicted, and assist all who come under their care to be hale, hearty and happy. Any class of men who exert themselves to this end is deserving our sympathy, support and cooperation. They who would help others and make them happy should themselves possess healthy bodies, cheerful countenances, and give hearty greetings, laugh and be happy.

Among physicians none antedate the allopathists or regular physicians. They have spared no expense in obtaining their education, nor placed any limit to their researches or modes of treatment. They have investigated man, his mechanism, composition, constitution, and differentiation in every manner imaginable, both physically and mentally. They have examined the kingdom of Nature, if not thoroughly, yet more thoroughly than any other class of physicians, in order that they might have all that could be obtained to prolong life and procure health and

happiness. When we consider our extensive research and labor, can we not claim the name pantherapist? We are so in practice; why not in name?

Other classes of physicians have not been idle. The homeopathists, although their system at first appearance is diametrically in antagonism to ours, have brought to light much useful information. They have had success in pedriatics, and many a living mother and father are untiring in their praise of the homeopathist for having restored their children to health when others have given them up to die.

The osteopathists also command our attention in restoring to health those whom many physicians thought and pronounced incurable; by their system, it is claimed, a better circulation of the vital fluids is produced.

There are others whose aim it is to cure disease, and whom we believe to be honest in their convictions, as the eclectic, the electrotherapist, the heliotherapist, the hydropathists, and others.

In fact, I believe it is our duty to honor and respect those who teach openly that which they believe, but I have no faith in those who practise their arts (if they have any) in secrecy.

As an individual I must protest against what is termed "Christian science" and "faith cure" as an outrage upon civilization, as a farce played to delude the ignorant, and as a cause of many an untimely death from neglect of proper treatment. Christianity and faith I believe are both necessary for our eternal happiness and for our spiritual existence; for our physical existence physical remedies are wanted, and these the Almighty has lavishly provided for us to take advantage of. The Christian scientists and faith curists are the only ones so far as I am personally concerned, whom I would not be willing to have enter the pantherapic ranks.

Should such a union of earnest, honest physicians take place, though holding different opinions, the result would be in many respect advantageous, because (1) a better acquaintance with one another would be established, and this would promote an interchange of ideas, and (2) in union there is strength.

Then let us measure idea either with or against idea. Though we who contend may each die with our individual ideas, yet those who examine that which we have said or written will be able to select the truth, or approximate it. Truth will stand the jar of all opposition and they who will hold it need not be backward in speaking or writing it.

Let the regular physicians organize and invite all who are honestly practising the healing arts to unite with them, the only demands to be made upon the members to be fee sufficient to cover necessary expenses and to comply with the rules of the order. After a set time, and when we are acknowledged as a body of regular practitioners by the legislature, let none enter our ranks without an examination by a board of at least six members and a president. Let the motto of our order be. "Prove all things. Hold fast that which is true."

Then, were it left to my choice, I would require answers on the following subjects from those who desired to unite with us: Human anatomy, morbid anatomy, regional anatomy, chemistry, physiology, histology, toxicology, obstetrics, description of diseases, classification of diseases, diagnosis of diseases, minor surgery, and at least twelve of the most important medicines selected by the board from some first-class materia medica, as approved by them.

It is better to have few tools and know how to use them than a great many and not understand their uses.

The course of examination would probably be enlarged by questions added from works that the allopaths have never handled, but let no questions be propounded, unless either text-books can be procured on the subjects or printed lectures may be had. This will call for neotherapeutics.

Neotherapeutics.

Neotherapeutics (νεος, new, and θεραπευταχη care) does not necessarily change the *modus operandi* in the treatment of diseases in which drugs only are used, but in using other treatments the change is marked. Very often two or more modes of treatment are so combined as to restore the patient to health in a few days and also to afford a pleasure to the invalid during his illness.

A great revision in medical remedies should be considered. We have, in fact, so many medicines to think of that we become sometimes almost lost when the time comes for selecting something for a particular case. Not the question, "What is good"? but, "Which is best"? Many of our medicines, too, should become obsolete, or kept only as a curiosity for the medical antiquarian. Others which have been dropped should be brought into prominence, as bole armenia, which by its peristallic action on the intestines, triturated with quinine, might be classified with the specifics in the cure of typhoid fever. No cathartics are needed.

Dakota is young, only entering upon her years of manhood, and her young physicians have sprung from as noble stock as Eastern States ever possessed, and with expanding talents have as good a right to form a broader platform than ever yet was formed and enter thereon as any had in past ages. Organize. Discard the doubtful medicines. Select those thoroughly tried and approved. Let us profit by the experiences of others, and remember your remedial agents should be as varied as your patients are. What would you think of a man who would attempt to repair a watch with such a set of tools as they repair locomotives with? And what do you think of men who attempt to repair the health of strong and vigorous men, when temporarily ill, with the same remedial agents with which you would attempt to restore the health of babes?

Let prejudice no longer fill our minds to cause us to think that we are the lords of creation, and

that "when we perish wisdom will perish with us." Others may be as wise perhaps wiser than we are, but their wisdom runs in another channel than ours. If we receive from them that which they have and impart to them that which we have, both will be benefited.

Variety is one of Nature's laws. Think of the variety of esculent plants that grow in one garden, or on one continent or in the world, all used for food, each having its peculiar habits and each adapted to the people with whom it is found. Each when eaten has its peculiar effects on the human system, when properly selected, masticated and digested, each particle helping to repair the waste of the body, and in turn improperly used these very foods produce pain, sickness, and finally death.

The physician, then, ought to be an instructor and teach the healthy to remain as they are and the sickly how to live. When proper food will restore health, do not resort to medicine. When a sound mind is required, give proper mental food or rest of mind, as may be necessary; these failing call in a specialist.

I think it was Cowper who wrote, "Lands separated by a narrow frith abhor each other, and mountains make enemies of nations." The railroads and steamboats have done away with Cowper's times. May not also *mental railroads* and newspaper navigation do away with the opposition that has existed among physicians and lay a broader platform than ever yet has been laid? All are needed who can render help in the cure of those who are diseased, either mentally or physically. May we not call that platform pantherapism?

"What are you going to do with the allopathists," says one, "dispense with him?" Not by any means. If the different therapies have severally saved lives by the hundreds, allopathy has saved its thousands. And the allopathist who can show himself skilled in his profession should be a specialist and entitled to special fees. Write iatropist (ιατρος) after his name. Give honor to whom honor is due and let each class have its own specialists. All specialists, then, should rise from the platform of pantherapism. On this platform each man has an opportunity of becoming broad-gauged, so when he rises above this stage to special work and needs assistance he will better know what other specialist or specialists to call to his aid. The young pantherapist should have resort to but few medicines, but necessarily twelve and not exceeding twenty-five. This number will not require much time to master, and should not be considered burdensome to the osteopathic, the electrotherapist, the hydropathist, the hysteropathist, or any other specialist or practitioner who may at times require them, and in the hour of danger he will be enabled to make a judicious decision.

Learn from the little sapling which expands its roots in every direction, some running deeply into the earth for water and minerals, others through the sands and alluvial deposits, drawing nourishments from the various foods that Mother Earth keeps in her cupboard, receiving just enough and no more than is necessary to satisfy its requirements, growing day by day, spreading its numerous branches, gladdening the hearts of men, and continues to grow until it stands proudly as high as the tallest trees around it, and finally may tower even above its fellows on account of its nutritious diet.

Let the young physician draw sustenance from every branch of the healing art, so that by reason, comparison and experience with the wholesome diet he has received from every source, whether from the mental, moral or physical world, those who come under his care may know and feel that the sources from which he has drawn his knowledge are not shallow, but deep.

A CASE OF DOUBLE PENIS, COMBINED WITH EXSTROPHY OF THE BLADDER AND SHOWING FOUR URETERAL ORIFICES.[1]

BY CARL BECK, M.D.,
OF NEW YORK.

THE case which I present is unique. There are only two cases of double penis on record—one by Velpeau[2] and William Acton[3] and the other by Küttner.[4]

In Velpeau's case a child of six months had two well-developed penes. There was also a supernumerary leg. The urine was discharged synchronously from both urethræ. Velpeau assumed that there was only one bladder.

Küttner describes a specimen taken from a newborn child which showed two scrota, each of

FIG. 1.

them containing one testicle. The two penes were well developed. There was one bladder from which originated the urethral channel, surrounded by a normal prostate. There were also normal seminal vesicles. Just in front of the prostate the bifurcation began.

In my case not only are two well-developed penes present, but there are also four ureters, which can be examined the more easily because there is a complete exstrophy of the bladder

[1] Presented before the Surgical Section of the Academy of Medicine.
[2] Journal des Connaissances Medico-Chirurgicales, XIV., 39.
[3] Medico-Chirurgical Transactions, London, 1848, 103.
[4] Beiträge fur Klinischen Chirurgie, Band XV., Heft 2.

(Fig. 1). The child is five weeks old and was born of poorly nourished parents who emigrated from Russia three years ago. There is another child two years of age. The baby shows no other abnormality; it is small, but fairly well-nourished; it is breast-fed.

Upon examination two ureteral orifices are seen at the lower margin of the everted bladder-wall, directly above the symphysis and slightly to the left. They protrude considerably. Each one resembles, in shape as well as in color, a small vaccination pustule, the light color contrasting with

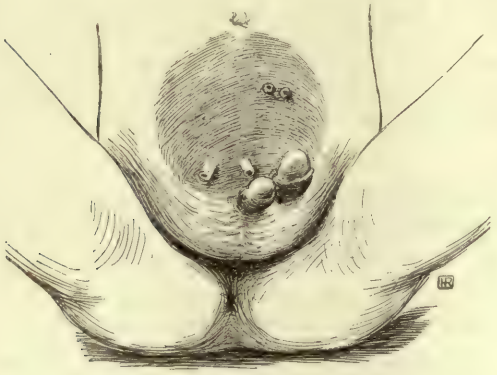

FIG. 2.

the dark-red mucous membrane of the bladder. The distance between the bases of the two urethral projections is three-fourths of a centimeter. Two small protrusions resembling them are found at the upper third of the exstrophied surface on the right near the upper border of the mucous membrane (Fig. 2). They project somewhat less than the other two and their orifices are a little smaller. The distance between them is ½ centimeter.

Both lower ureters discharge urine in the manner usually observed in exstrophy of the bladder.

FIG. 3.

Once in a while, especially when the child cries, a stream of urine about ten centimeters long is discharged from the ureters. The left ureteral orifice is a little wider than the right one, and apparently the stream from it is larger than that from the other. On introducing a probe into each of the lower ureters the impression of the presence of a small receptacle is given. A thin flexible probe cannot be introduced further than three centimeters.

The upper ureters functionate differently. A probe can be introduced into both to a depth of a little more than one centimeter. Urine has not been detected at the median orifice, but once in a while a drop issues from the external one. The trigonum Lieutaudii is pronounced neither at the upper nor at the lower urethral region.

At the inner surface of the symphysis, partially covered by the protruding bladder-membrane as well as by the scrotal folds, are two well-developed penes, placed side by side. It is only after pulling the latter downward and the mucous membrane upward that they both appear conspicuously (Fig. 3). They are of different sizes. The larger one has greater dimensions than could normally be expected in proportion to the age and size of the child. The direction of the basal insertions is toward the left, as if they would merge into left Poupart's ligament. The length of the larger penis is three centimeters from its symphyseal base to the top of the glans; that of the smaller one is only two.

The glans of each penis is very well developed; there are no adhesions of the membrane to the surface of the glans. The urethral orifices are normal within the extent of the glans. A probe can be introduced a distance of one centimeter into the larger and three-fourths of a centimeter into the smaller penis.

That both penes contain erectile tissue became evident from the well-marked erection which was observed shortly after the operation for exstrophy of the bladder. The bases of both penes show a cartilaginous consistence and give the impression that a bulbus is present. The relations to the rectum appear to be normal. Whether the prostatic gland and seminal vesicles are also present, I am not yet able to determine.

A skiagraphic examination showed a considerable gap in the symphysis. There is a very large scrotum divided by a well-marked raphe. Between the two penes is a large groove which creates the appearance of a second sac. A further report of the case will be made after operation.

A CASE OF CONGENITAL ABSENCE OF INTERNAL GENITALS; FUSION OF KIDNEYS; SINGLE URETER.[1]

BY ALLEN J. SMITH, M.D.,

AND

WILLIAM GAMMON, M.D.,

OF GALVESTON, TEX.

THE specimen to be described (No. 42, Pathological Museum, University of Texas) was obtained from the body of an American-born girl, M., daughter of Italian parents, dead at the age of sixteen years from an attack of tetanus. She was brought into the surgical wards of Sealy Hospital under the care of Prof. James E. Thompson, Nov. 22, 1894, and died fifteen days after admission. After death autopsy was not permitted

[1] From the Pathological Laboratory, University of Texas, 1901, No. 4.

by the parents; but the absence of the vagina having been discovered while catheterizing the patient by one of the writers (W. G.,) at the time house surgeon in the hospital, a postmortem perineal operation was performed and the specimens obtained in this way. In the haste and difficulty of manipulation the ureter was cut and exact examination of the pelvic cavity and renal region impossible; but, in the brief investigation afforded, no structures of ovarian, uterine, liga-

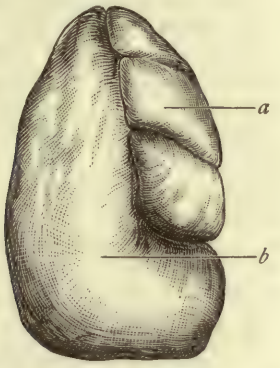

FIG. 1. Fused Kidneys, ventral view; *a*, smaller, probably left, organ; *b*, larger, probably right, organ.

mentous or tubal nature could be detected, and no cord-like structures could be seen or felt to represent these parts, and it is believed that nothing of the sort existed.

The condition of affairs is fairly represented in the accompanying diagrams. There was but one kidney mass (Fig. 1, anterior aspect of kidney; Fig. 2, posterior aspect of same, showing pelvis and beginning of ureter and renal vessels), occupying the position of the right organ. This

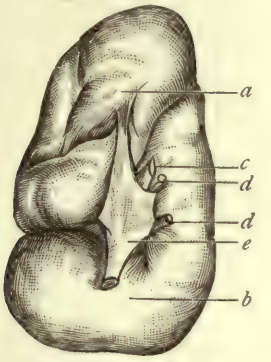

FIG. 2. Fused kidneys, dorsal view; *a*, smaller organ; *b*, larger organ; *c*, renal view; *d*, renal arteries; *e*, pelvis serving for both of the fused kidneys, provided with single ureter.

organ weighed a trifle over two hundred grams; measured 12 cm. in greatest length, 7.5 cm. in width, and 5 cm. in thickness at thickest part. From the size and shape one is led to regard this mass as the result of fusion of the two organs (fusion of right and left metanephra). In Fig. 1 and Fig. 2 the portion marked *a* corresponds with what should have been the left kidney; that marked *b* with the true right kidney; the letters *c*, *d*, and *e* in Fig. 2 marking respectively the renal vein, renal artery and pelvis of the kidney. Careful search through the perineal opening was made for a possible kidney upon the opposite side, but none could be detected and but a single ureter could be found, the bladder showing no trace internally or externally of other ureter than the right one, which opened in the usual situation. This ureter was in every way normal in appearance; at its superior end it opened into the pelvis of the fused kidney as indicated in Fig. 2. The pelvis included two major cavities, a superficial one from which the ureter arises (into which two papillæ of the superior portion of the kidney, *a*, opened), and a deeper part extending between the two portions of the kidney mass (into which all other papillæ of both parts of the fused organs projected); the latter pocket communicated with the first by two openings, each about 3 mm. in diameter.

The external genitals (Fig. 3), while perhaps

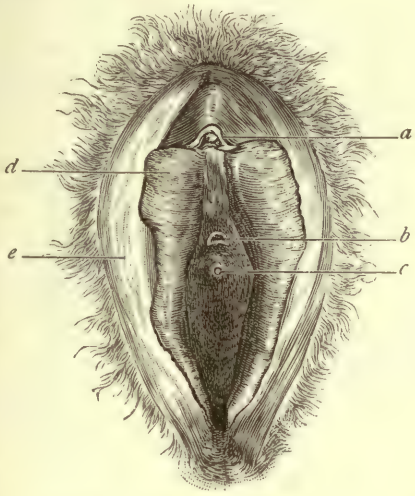

FIG. 3. External genitals; *a*, clitoris; *b*, meatus; *c*, opening of rudimentary vagina; *d*, labium minus; *e*, labium majus.

smaller than might have been expected, were of perfect conformation, and the usual pudendal hairs were present in appropriate number. On separation of the labia (Fig. 3, *d*, labium minus; *e*, labium majus), however, while a clitoris (Fig. 3, *a*; Fig. 4, *d*) of normal size and position and a normally situated meatus (Fig. 3, *b*, Fig. 4, *c*), of usual appearance are seen, the vulva appeared merely as a shallow pocket (Fig. 3, *f*; Fig. 4, *g*), measuring from anterior to posterior commissure eight centimeters, with a greatest depth from the convex surface of the labium minus of one centimeter, this depth being attained in the posterior third of the *cul-de-sac*. In the wall of this vulvar pocket, immediately back of the meatus urinarius, there was a small papilla into which extended a tiny tube, admitting a small pocket-case probe to a distance slightly less than one centimeter and ending blindly in the fibrous structures surrounding the urethra. (Fig. 3, *c*; Fig. 4, *h*). This tube is

the representative of the vaginal canal. Upon removal of the specimen the posterior wall of the bladder and the anterior wall of the rectum were found closely approximated, the intervening space extending down to the perineum being occupied by loose fibrous and adipose structures, and there could be found nothing in the least suggesting rudiments of uterus, tubes, broad ligaments or ovaries. The base of the bladder and the urethra (the latter measuring two centimeters in length) were surrounded by a somewhat increased amount of dense fibrous tissue, in the midst of which the rudimentary vagina terminated blindly; and while no microscopic examination of this tissue was made, careful dissection did not reveal trace of any structure suggestive of the missing parts.

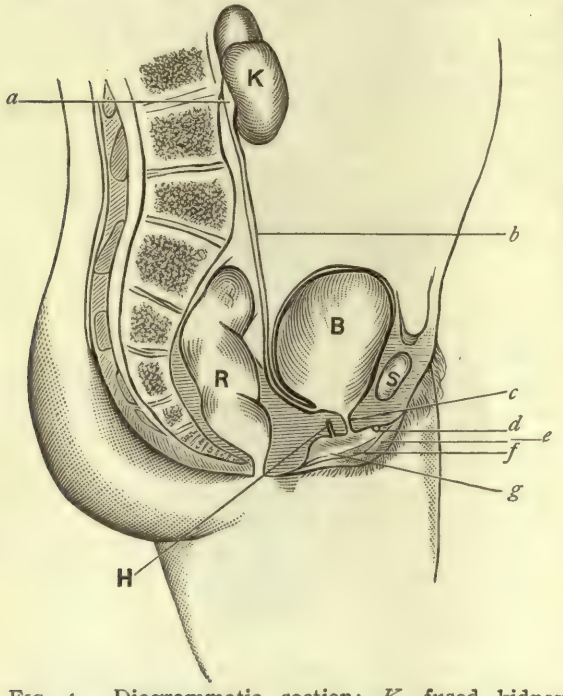

FIG. 4. Diagrammatic section; *K*, fused kidney (occupying situation of right kidney); *R*, rectum; *B*, bladder; *S*, symphysis pubis; *H*, rudimentary vagina; *a*, pelvis of kidney; *b*, ureter; *c*, urethra; *d*, clitoris; *e*, labium majus; *f*, labium minus; *g*, pocket of vestibulum of vagina (vulva).

It is not impossible that some ovarian rudiments in the pelvis or higher up near their place of origin in the lumbar region might have been found had it been possible to dissect the body with the usual freedom of a postmortem examination; but careful search was made by palpation through the perineal opening without avail, and the writers believe that none existed.

As far as could be determined no knowledge of the existence of this abnormality was possessed by the girl or her friends. She had always maintained fair health, but had never menstruated; nothing suggestive of vicarious menstruation could be learned after her death. The body presented the usual feminine configuration, and the mammary glands and mons veneris were amply developed. Private information stated that the girl had frequently indulged in some type of intercourse with males, and that she was of passionate nature. How coition could have been satisfactorily accomplished is difficult to understand; and why the malformation was not at such times detected is likewise a problem. Possibly it was known secretly, but no information could be obtained upon this line.

It is unfortunate that a closer examination was not permitted with a view of possibly determining some factor in the cause of the malformation. One may surmise that perhaps an inflammatory process in the upper abdominal area, corresponding with the anterior parts of the Wolffian bodies, existed in early embryonic life, destroying the pronepheron and mesonephron of each side, and causing the formation of adhesive bonds between the metanephra resulting in the eventual fusion of the kidneys. How to account for the utter absence of the ureter on the left side by such a supposition is difficult to understand; yet it is not beyond the bounds of conjecture that such inflammatory change could have caused sufficient alteration in the left metanephron to prevent the growth of the Wolffian duct, and yet not entirely destroy the essential structure of the former and its chance of partial development. The small size of the upper part of the renal mass, which the writers regard as representing the left kidney, would suggest that such partial involvement of the primitive kidney is not impossible. An investigation of the relation of surrounding structures to the renal mass, of the position of the abdominal vessels and their conformation, and of the bowel wall, for a possible remnant of this left Wolffian duct might have thrown further light upon the subject.

The attack of tetanus from which the subject died was believed to be due to infection of an ulcer of the leg. The course of the case was peculiar in that after some days in the hospital under the usual treatment of chloral and the bromides, the tetanic symptoms disappeared, but the patient's general condition did not improve and several weeks after entrance she died from exhaustion. Probably dependent upon the infection, and also probably a factor in the death of the girl, should be mentioned a moderate degree of cloudy swelling of the kidney, apparent both grossly and microscopically in the specimen described.

A FEW REMARKS ON A GENERALLY UNRECOGNIZED EAR DISEASE (OTITIS MEDIA MUCOSA.)[1]

BY HENRY A. ALDERTON, M.D.,
OF BROOKLYN, NEW YORK.

DURING the winter 1900-01, because of the great prevalence of grippal and ordinary colds, the writer's attention was repeatedly drawn to the unusual frequency of exudative, non-perforative otitis media. The past year, in his experience,

[1] Read before the Am. Lar., Rhin. and Otol. Soc., N. Y., May 24, 1901.

because of the increased virulence of the causative nasopharyngeal inflammations, the type has inclined more to the mucous than to the serous form of exudative inflammation. And, for this reason, its recognition has been attended at times with much greater difficulty. Unlike the serous exudative inflammation, *otitis media serosa*, the mucous form appears to occur relatively more frequently in adults.

Following a severe cold, grippal or otherwise, the patient begins to have trouble with one or both ears. Possibly this may take the form of an evanescent earache, which yields quickly to the ordinary or extraordinary home remedies; in other cases no pain at all is noticed. Tenderness to touch of the parts around the auricle is more common and frequently recurs during the early part of the disease. In a day or so, whether there has been earache or not, hardness of hearing makes itself manifest, together with a feeling of stuffiness in the ear, as though the external canal were plugged, and a feeling of fulness, both in the ear and over one or both sides of the head, according as the affection involves one or both ears. Frequently there is present an intense tinnitus, which is either hissing or pulsating; often the tinnitus is likened to escaping steam. There is usually no sensation of throbbing, such as exists so often in an acute purulent otitis media. Because of the stuffiness and full feeling in the head, cerebration is difficult and concentration is a lost art. Autophony is usually noticed. Cracking sounds on blowing the nose or swallowing are not so frequently observed as in the serous condition, probably because of the greater degree of tubal obstruction. The patient is unhappy, fearful for the future and, because of his infirmity, unable to attend to his business. The hearing becomes so badly involved that the watch is heard not at all or only close to the ear and conversation is indulged in only at the cost of considerable exertion on the part of the patient's family and friends.

If the exudation is formed rapidly and in considerable quantity, mild vertiginous attacks may occur. These attacks are not severe and mostly consist of a dizzy feeling, sometimes occurring on changing the bodily position. There is none of the other phenomena associated with Ménière's symptom-complex.

Because of the patient's anxiety for relief, he usually calls upon the aurist during the first week of the disease. On examination, after the removal of whatever detritus maceration and home remedies have evolved in the external ear canal, one finds that the osseous canal wall, unless irritated by overtreatment, has very little congestion and there is no swelling. There may be slight tenderness over the tragus or over the position of the Eustachian tube in the neck. The tympanic membrane is seemingly in about its usual position, neither retracted nor bulged to any appreciable extent. As a whole it may be pushed out a little more than normal toward the canal. The luster is gone, the surface has a dull gray, leaden appearance. Surrounding this dull gray field is a ring of congestion and coursing across the field are a number of separate capillary, twigs beginning at the periphery and disappearing towards the *umbo*. Along the hammer handle the malleal plexus is unusually pronounced. This hyperemia does not resemble, except remotely, that of a beginning purulent otitis media; it is dull and grayish red, not brilliant and distinct as in the latter affection. Schrapnell's membrane does not seem to be markedly affected. There is absolutely no fluid line discernable, nor can the presence of fluid be made out by any difference in the appearance of the various sections of the drum membrane.

Functionally, the ear is apparently very gravely involved. The watch is not heard or only on contact or very close to the ear. The whisper is heard for a very short distance, but the hearing for the spoken voice is relatively somewhat better. Bone conduction, for the Hartmann series of tuning-forks, is normal or better. The lower tone limit is impaired, even up to the C fork (128 d.v.s.), in certain cases. The upper tone limit is apparently very little, if at all affected. The intensity Rinné test shows as negative (that is, initial BC is heard better than initial AC), in marked cases as high up on the scale as the C^8 fork; rarely, the C^4 fork may give an equal reaction. The duration Rinné is likewise negative for the lower forks. In a unilateral affection, Weber's test is positive.

Examination of the nasopharyngeal cavities shows an active or retrogressing inflammatory process. The pulse and temperature are practically normal. Such a condition may endure, in various degrees, for from only a week or two up to a matter of years; in one of the writer's patients the condition had never entirely disappeared for about nine years. During exacerbations of the trouble the symptoms are as already detailed; with the subsidence of the congestive period the radiating vessels disappear, the drum membrane becomes uniformly a dull gray and remains thick and opaque, and the functional ability is slightly improved.

Change in the position of the patient's head does not induce the improvement in the hearing which is sometimes noticeable in cases of otitis media serosa. Inflation of the tympanum improves the hearing, though only temporarily, and never to the degree usually seen in the serous process. During the process of inflation mucous crackles can usually be heard with the otoscope.

Incision of the tympanic membrane alone sometimes gives exit to no secretion or to only a little teat-shaped projection, hardly visible through the hemorrhage from the cut edges. The drum membrane is often so thick and fibrous that considerable force is necessarily exerted in order to penetrate into the tympanum. But on forcible inflation the picture is changed. Then there appears in the canal a quantity of stringy, tenaceous mucus which follows the cotton on the applicator on its withdrawal from the canal as a long, fila-

mentous string, for a distance of a number of inches from the external auditory orifice before it finally consents to part company. Often, in order to evacuate the drum cavity, it is necessary to inflate forcibly and repeatedly, assisting the extrusion of the mucus with the cotton applicator or with suction. After the removal of the exudate the hearing is immediately greatly improved and remains so until the incision heals and more mucus is formed.

Douching alone through the external canal has never seemed to do other than harm, in the writer's experience. Periodical inflation, combined with treatment of the nasopharyngeal condition, will in a certain proportion of cases bring about a slow recovery, but often the patient is not willing to await the results of so slow a process and gravitates from one to another practitioner, the true condition frequently being unrecognized, until permanent impairment of the function of the ear results from the inspissation of the exudate or the formation of adhesions or the deposition of connective tissue in the mucous membrane of the tympanum by reason of the prolonged hyperemia.

Certain systemic remedies seem to be of benefit; such, for example, as the iodide of potash in increasing doses. But the treatment *par excellence* consists of incision and evacuation of the tympanum, repeated if necessary and always accompanied by regular politzerization and conscientious treatment of the nasopharyngeal condition. The relief is immediate and, while subject to temporary setbacks, permanent for the current attack. Before incision the external auditory canal should be made as nearly aseptic as possible by syringing with a tincture of green-soap solution, following this with instillation of absolute alcohol and then by syringing with a 1-2000 bichloride solution. The canal is then packed with aseptic gauze and the patient sent back to the waiting-room for half an hour to await the subsidence of the increased hyperemia necessarily induced by these procedures. The patient is then subjected to a thorough cleansing of his nasopharyngeal cavities. The gauze packing is removed and under good illumination a thorough incision is made with a sterilized knife along the inferior segment of the drum membrane just internal to its attachment to the *annulus*. The ear is inflated and the mucus removed by means of sterile cotton pledgets. Finally, the canal is again packed with aseptic gauze, covered outside by a cotton pad kept in place by adhesive plaster. A mild astringent application of a solution of silver nitrate or glycerite of tannic acid or the stronger glycerite of tannic and carbolic acids is applied to the postnasal mucous membrane.

The patient must be seen in from twelve to twenty-four hours and the ear again gently inflated and the gauze packing renewed. After this, a treatment once in every two or three days is all that is usually necessary. Often the drum membrane may have healed by the first dressing.

Should the exudate persist in reforming, a solution of nitrate of silver, ½ to 1 grain to the ounce of boiled distilled water, acts favorably, both injected into the Eustachian tube and instilled into the tympanum through the incision. The writer has never seen undue reaction follow this procedure, if the previous steps have been faithfully carried out.

142 Clinton Street.

THE LOCAL TREATMENT OF GONORRHEA.[1]

BY E. O. BARDWELL, A.M., M.D.,
OF EMPORIUM, PA.

ONE of the most disagreeable diseases, one of the most unsatisfactory and annoying complaints that the general practitioner is called upon to prescribe for, is gonorrhea in the male. It is a disagreeable disease *per se*. It is often quite difficult to secure a satisfactory result in a reasonable time with ordinary remedies, even when directions are carefully followed, and it is almost invariably impossible to exercise such supervision over a case as to be at all certain that directions are followed with any care whatever.

When a case is cured in two or three weeks the physician receives no particular credit, as it is supposed to be no more than any physician can do, if he wants to. When, however, the thing runs along for several weeks, as it mostly does, then the curses hurled at the devoted doctor's head are many, loud, and deep.

During an active practice of twenty-two years I have seen a large number of cases of gonorrhea and have witnessed quite a good many attempts to cut the disease short in its incipiency by the use of strong injections. I do not know that I have ever seen a clear-cut success when the case was beyond doubt a genuine gonorrhea. I do know, however, that I have seen quite a number of horrible failures. One in particular, which always occurs to me when on this subject, was that of a young married man, who, when the indubitable proof of his moral obliquity stared him in the face, followed the advice of a friend and passed a solid stick of lunar caustic into his penis. He withdrew it at once, of course, and the evening of the same day he came to me with his penis about three times its normal size. It may be set down, in my opinion, that the aborting of cases of "clap" by the use of strong injections is uncertain, unsatisfactory, and dangerous, and ought never to be attempted, at any rate in a first attack, and in a mild case using injections or irrigations of more than an ordinary strength can do no good and is very likely to be productive of injurious results.

For twenty years copaiba and oil of sandalwood, separately, or in combination, have seemed to me to have a good effect in the first stage of gonorrhea. In many cases, however, the good effect proved only transitory. The copaiba very often nauseates and sometimes cannot be tolerated at all. In these cases spirits of turpentine, two

[1] Read before the Elk County Medical Society, Ridgway, Pa.

or three drops in combination with cubebs in an emulsion, taken largely diluted has seemed to have a beneficial action. Sandal-wood oil often causes severe pains in the lumbar region and probably at least ninety-nine times in a hundred these remedies alone do not cure genuine gonorrhea, and local remedies must in the end be resorted to. Turpentine, copaiba, and cubebs are entirely too stimulating and irritating, both locally and generally, to be passed into the stomach and blood and strained through the kidneys for the relief of a local lesion situated from one to two inches back of the glans penis, unless the indications for such use are clear, unmistakable, and practically mandatory.

From this point of view all internal specific medication in gonorrhea should be abandoned. These remedies do benefit the local lesion when given in sufficiently large doses; there can be no doubt about that, but when so given they almost invariably derange the stomach and weaken the kidneys, and the undue stimulation of any normal organ is always to be deplored. I have seen many cases in which the digestive disorders and the irritability of the kidneys have continued for years after the ingestion of these drugs had been stopped, and even though there were no other way to cure gonorrhea it has often seemed to me that the administration of these drugs was a doubtful service to the patient. There appears to be, however, in nearly all cases, an undue acidity and concentration of urine that requires the use of a mild, bland, unirritating diuretic, especially in the first stages of the disease, and for this purpose ten or fifteen grains of citrate of potash, either alone or combined with hyoscyamus, will usually be found to answer every purpose. Of course, lithia or sodium may be used in lieu of the potassium if preferred.

I do not know if this condition is due to financial prosperity, the Spanish War, or to commercial expansion; but I do know that I have seen an unusually large number of cases of gonorrhea during the past year, and some of my confrères have also noticed the increased number of these cases prevailing during the year 1900.

In May, 1900, I commenced using protargol as an injection in gonorrhea and since then my results have been more satisfactory than before. It has proved most satisfactory to me in a solution of two grains to the ounce of water, and in this strength I have in many cases begun using the injections the first day of the disease. In two cases which were primary and unusually severe, I gave citrate of lithia internally and morphine by injection into the urethra, for thirty-six hours before commencing the protargal.

The old injections, tannin, silver nitrate, copper, lead, zinc, and hydrastis, I had pretty nearly abandoned several years before, and had used permanganate of potassium with more or less varying success; but I must say that protargol seems to me to be the ideal injection, and in the few cases in which it has not given good results I have found an error in administration. I have used protargol by injection in preference to irrigation, not only because the results appear to be better, but also for the reason that the injection method is much more convenient and the patient is very much more certain to use the treatment thoroughly, and as for the method by irrigation there are many cases that are so situated as not to be able to come regularly to a physician's office, and I have neither the time nor the inclination to give these patients my personal attention every time they need an irrigation.

A few case reports may prove of sufficient interest to justify their reading at this point.

Case I.—The patient came to me the day after he noticed a urethral discharge; he had been in the same predicament before, but professed to be greatly surprised. I prescribed a solution of protargol, one-half of one per cent., to be used three times a day in a proper syringe; patient reported in eight days with no apparent improvement. Strength of solution was then increased to one per cent. injected three times a day; reported again in six days, improvement very slight. I then learned that owing to the patient being an old hand at the business I had not sufficiently instructed him in the *modus operandi.* I directed him to immerse the bottle of solution in a basin partly filled with warm water a few minutes before each injection, or until the solution reached a temperature of from 100 to 110° F.; to urinate before injection; to fill the urethra with the solution and then compress the glans penis and retain the solution five minutes; wait a couple of minutes and then repeat the process; to take this double injection three times a day and report again in five days. He did so, reporting at the end of five days that the discharge had nearly ceased, and he was entirely well three days later.

I find that when patients have previously used injections for gonorrhea it is almost invariably necessary to insist quite strongly on the importance of using the solution freely and of retaining it a sufficient length of time. They have been accustomed to using solutions that bite and they are afraid of anything in the shape of an injection.

Case II.—This patient consulted me about four weeks after the discharge commenced; had been taking one of the old-style sandal-wood mixtures—in fact, an old one of mine that a friend had kindly loaned him—but he denied having used any injection; he was suffering from a severe attack of well-developed orchitis in addition to the urethral discharge which had to some extent subsided. I had him put to bed at once, the testicles properly supported, hot fomentations applied, and ordered an injection of a solution of protargol, one-half of one per cent. The discharge ceased in four days, although when the orchitis began to soften up, in about one week, the discharge again commenced and lasted three days longer, when it ceased entirely under the use of protargol and did not return as before.

Case III.—This patient was a married man who came with the access of the first symptom

and wanted the disorder throttled. I gave him a one-per-cent. solution of protargol to inject, warm, three times a day, two syringefuls each time and told him to report in a few days. He came back in four days and reported the discharge as rapidly diminishing, and in six days said it had ceased entirely. I advised him to continue the injections six days longer, one syringeful three times the first day, twice the second, third, and fourth days, and once at bedtime, the fifth and sixth days, then to immerse his testicles and penis in cold water every night before retiring for a week, and report again. He reported in a week and said there had been no re-appearance of the discharge and he felt sure that he was all right; however, he returned again in two days with a slight discharge, when I increased the strength of the solution to two per cent., one syringeful at bedtime and in the morning, which he used five days, the discharge stopping the second day. At the end of the five days he used the injection four days longer, and abstained from sexual intercourse another week, and has had no further trouble, neither has his wife shown any signs of infection and nine months have now passed.

Case IV.—Young man who expected to be married in a few weeks; first attack; discharge not yet in evidence, but soreness, swelling, redness, and frequent and painful micturition. Citrate of potassium in ten-grain doses, largely diluted, ordered every four hours internally, and a solution containing protargol, one-half of one per cent., and sulphate of morphine, one-fourth of one per cent., as an injection every four hours. After the fourth injection the morphine was left out entirely, and the case progressed very rapidly to a satisfactory termination. The discharge, which commenced soon after I first saw the patient, increased for two days, then subsided and stopped entirely on the sixth day. There was chordee the night after the morphine was discontinued, but it was easily managed.

Case V.—Ordinary typical case of gonorrhea; patient said that he was not surprised and that he deserved nothing less; said when he had had the same old thing previously it had usually taken about six months to get over it, and that he would appreciate my kindness if I would try to do a little better than that. I gave him lithia tablets, five grains each, to take one every four hours in a tumbler of cold water, and an injection of a one-grain solution of protargol to be used warm, three times a day, two syringefuls each time. There was a slight improvement at the end of one week, when the strength of the solution was increased to one and one-half per cent. for another week when the discharge stopped and did not return.

Case VI.—Similar to Case V., except that the discharge had already continued six weeks when I was first consulted. At the end of the first week the injection was raised to strength of two per cent., and at the end of the second week the discharge, having very materially diminished, it was continued at this strength for another week, when the discharge entirely ceased. The injection was then continued in a one-per-cent. solution three days, and then in half that strength for four days longer, when it was discontinued and no further trouble followed.

Case VII.—Essentially the same as the last two, except that I mistrusted that the patient did not refrain from intercourse as I had instructed him to do. The discharge in this case had been running three weeks when I first saw him. I commenced with a one-per-cent. solution of protargol, increased the second week to a two-per-cent., and at the end of the third week, the discharge not having entirely ceased, I prescribed permanganate of potassium, two grains to four ounces of water, and at the end of another week patient was discharged cured and has since remained so. I am not sure that he would have recovered just as rapidly had the protargol been continued instead of resorting to the permanganate of potassium.

I have only treated thirty cases of well-marked undoubted gonorrhea since I commenced the use of protargol, and, although I have finished up in three of these cases by using potassium permanganas, typical samples of the entire thirty cases are given above, and it will be seen that there is no evidence to show that the potassium was really of any assistance. I would probably not have resorted to it at all but for the fact that prior to the beginning of the use of protargol the potassium permanganas had been more favorably considered by me than any other local remedy I had used in gonorrhea up to that time.

Members of this Society who are personally acquainted with the writer will probably not be at all surprised at his failing to allude to the use of the microscope as an assistant in the diagnosis of gonorrhea. To others, however, it may not be amiss to state that I utterly fail to see the immense benefit that is said by some physicians to follow the use of the microscope in this disease. The great majority of physicians who treat gonorrhea could not tell a gonococcus from any other coccus in any event, and as affording sure evidence by which we may be able to protect the innocent party, where parties are married, I always protect the woman anyway so it makes no difference. In regard to the use of the microscope in diagnosis it is my opinion that a doctor who has been in practice twenty years and really requires a microscope to diagnose a case of clap has been in practice about twenty years too long.

In concluding this paper I wish to say that I believe that we have in protargol the very best local remedy yet produced for gonorrhea. The only cases in which it has failed in my hands to cure a case of gonorrhea in less than two weeks were cases in which there was an error in administration. I have found it is quite important that the solution be injected warm, and that it be used in large amount, an ordinary syringeful at each injection, and the injection made two times at a sitting, three times a day, the urethra being well distended, and the solution retained at least five

minutes. I have never seen any bad results from it in solutions as high as two per cent. and would not hesitate for a moment to use a five-per-cent. solution if I thought it necessary or advisable.

MEDICAL PROGRESS.

Purgatin.—Purgatin, the diacetate of anthrapurpium, according to H. VEITH, consists of a yellow, crystalline powder which is insoluble in water and nearly so in alcohol. This synthetic product causes mild purgation in twelve hours after 0.5-1.0 gram without concomitant pains or tenesmus. The patients are to be told of a yellow discoloration of the urine which is liable to set in. The tastelessness of the drug is a further advantage and it is especially recommended in chronic constipation and neurasthenia.

Experimental Ligation of Splenic Vessels.—Through extended animal experiments D. BALACESCU (*Münch. med. Woch.*, Aug. 27, 1901) finds that (1) ligation of all the vessels with the gastrosplenic ligament leads to generally fatal gangrene of the organ; animals may, however, withstand the intoxication,, when atrophy sets in after eight days; (2) ligation of the splenic artery or vein alone is usually stood well, since sufficient collateral circulation is maintained. The atrophy resulting is very slight and slow in developing, but more manifest if the vasa efferentia are narrowed.

Compression Therapy in Heart Disease.—Most clinical observers have noticed the manner in which patients suffering from heart disease instinctively seek relief from painful subjective symptoms by pressing the hand against the præcordium. Abée of Nauheim was the first to suggest the use of some form of apparatus to replace the temporary pressure of the hand by constant mechanical support. M. MENDELSOHN (*Berl. klin. Woch.*, Aug. 26, 1901) believes that the relief which such apparatus affords is not the result of any support or lifting of the heart, but depends upon compression of the chest wall. An amelioration of symptoms is obtained in cases presenting cardiac enlargement, with hypertrophy and dilatation of the left ventricle. In such cases the heart is in direct anatomical relation with the lateral as well as with the anterior chest-wall, and each movement of the heart is forcibly and directly communicated to these parts, producing a notable physical shock. Mendelsohn believes that the painful sensations experienced by the patients reside very largely in the hyperesthetic thoracic wall and not in the heart itself; hence the value of supporting the thorax in the cardiac region, and thus limiting the violent shaking of the parts. In addition, compression of the thorax, to a degree not inconsistent with freedom of respiration, is said to lessen excessive cardiac motion and to abolish disagreeable sensations dependent on such motion. A thorax-compressor has been devised by Dr. Graüpner of Nauheim. A plaster cast of the thorax is first prepared, and from this is cut the part which corresponds to the superficial cardiac area, overlapping this area by two or three finger-breadths at each margin. From this cast a metallic plate is prepared, and to the inner side of the plate a flat air-cushion, extending over the entire surface, is fastened. It is advisable to have attached to the air-cushion a rubber tube long enough to permit the patient to blow up the cushion when the latter is in place. The compressor is held in place by binders passing over the shoulders and across the back.

Trichinosis in the United States.—Although numerous epidemics and spontaneous cases of trichinosis have been recognized in the United States, the impression is still prevalent that it is an uncommon disease in this country. On account of the apparent lack of systematic research with respect to the frequency of the disease here, HERBERT U. WILLIAMS (*Jour. Med. Research*, July, 1901) has undertaken studies with regard to such occurrence. He examined 505 cadavers, death being caused by other diseases, and found trichinæ present in 27 or 5.34 per cent. He took samples from the muscles (sternocleidomastoid, psoas magnus, diaphragm and rectus abdominis). These specimens were usually about 3 centimeters long and 1 or 2 centimeters in thickness. These were immediately examined or preserved in cold storage or by a weak solution of formalin. They were then studied between plates of glass microscopically with the low power. All of the subjects were over 14 years of age. As all the subjects died of a disease other than trichinosis in every case the infection with the trichinæ must have occurred a considerable time previous to death. The infections were of various degrees of severity, sometimes being very extensive, while sometimes only a few worms were found. A large proportion of the cases were born and had always lived in the United States. An unusually high percentage occurred in insane patients. No eosinophilic cells were found about or near the encapsulated trichinæ. Most cells do not collect in or about the capsules in cases of old trichinosis. Newly formed elastic fibers and plasma cells sometimes are found in this location. The capsule may be invaded by new cells, the worms disintegrate and the capsule become filled with fibrous and adipose tissue. It is evident that many cases of old trichinosis escape detection at autopsies.

When to Operate on Gall-Stones for Radical Cure.—Leaving out of consideration the palliation of malignant or otherwise hopeless disease by the removal of pain-causing gall-stones, M. H. RICHARDSON (*Boston Med. Surg. Jour.*, Sept. 5, 1901) maintains that gall-stones should be removed at the earliest favorable moment after diagnosis, unless there are contra-indications in other viscera or in the patient's general condition. The "earliest favorable moment" is that period of time when there is no infection of the gall-bladder to contaminate the field, no impaction in the common duct to increase the dangers of

dissection and no jaundice to induce hemorrhage or to impair the patient's power of recovery. In favor of this author's proposition it may be said that (1) the operation as a rule is easy and safe; (2) the remote dangers of gall-stones are lessened or avoided; (3) if the diagnosis of gall-stones proves to be wrong, other lesions may be discovered and remedied—lesions perhaps even more serious than gall-stones; (4) late operations on gall-stones are as a rule difficult and dangerous. Operations made imperative by progressive and lethal symptoms must be performed under great disadvantages and dangers; the gall-stones generally are more inaccessible, the dissections deeper, and the patient's power of resistance lessened. While the possibility of spontaneous cure is not denied, Richardson believes that such cure, whether or not it is aided by medicinal treatment, is clumsy, dangerous, ineffectual and contrary to common sense. Once gall-stones begin to offend, there is no way of telling how the process will end; the chances are it will result in disability or death.

Bacteriology of Erysipelas.—The Bacteriological investigations of B. JORDAN (*Münch. med. Woch.*, Aug. 27, 1901) confirm the view that erysipelas is not a specific disease caused by a special bacillus, for experimentally staphylococci, pneumococci and colon bacilli have been found as cause in rabbits. In man the coccus generally found is the streptococcus pyogenes, but there are also undoubted cases where the staphylococcus aureus was the incitor. The question as to whether pneumococci, colon and typhoid bacilli are able to set up a true erysipelas in man must still be considered an open one. The author does not believe in drawing a sharp distinction between erysipelas and pseudo-erysipelas, but thinks that both are merely varying grades of severity of one and the same disease.

Bacteriolysis and Typhoid Immunity.—Typhoid fever is a self-limited disease and experience has shown that, except in certain organs of the body, such as the urinary and gall-bladders, the specific organisms disappear as convalescence approaches. The supposition therefore is that at this time the tissue cells and blood become more and more antagonistic to the bacilli and finally cause their destruction. However this may be inside the body, we know that it does not occur outside of it, for typhoid blood, from sick or convalescent patients, and bouillon make an excellent culture-medium for the bacilli. When, however, these are introduced intraperitoneally into a normal guinea-pig disintegration or "Pfeiffer's phenomenon" occurs. M. W. RICHARDSON (*Jour. Med. Research*, July, 1901) has studied this subject by the experimental observation of the combined effect upon the typhoid bacillus of typhoid blood which contains a specific immunizing element and normal serum which contains a non-specific normal ferment and shows that when they are properly combined they cause a destruction of the bacillus. In typhoid fever Nature produces a cure by the proper combination of these substances which are produced by the body-cells, especially those of the lymphatic apparatus. It is the function of the immune element to bind the non-specific element to the bacterial cell and thus cause its destruction. In the earlier stages of the disease the immune element may be abundantly present and yet be of little value because of the absence of the non-specific element or compliment. In the stage of falling temperature this compliment returns to the blood and a corresponding destruction of the bacilli takes place which sets free the typhoid toxin contained in the bacterial cells and possibly causes the remissions in temperature seen clinically during the fourth week. Inasmuch as the addition of normal serum to the inactive serum of typhoid patients will in most cases make it similar to that present in the fourth week we are justified theoretically in so treating typhoid fever. The immune element might, however, also be lacking in which case it would have to be supplied. This could be ascertained by proper investigation.

Surgery of the Diaphragm.—Two cases of incised wound of the diaphragm which were closed by suture and which recovered are placed on record by C. SCHLATTER (*Münch. med. Woch.*, Aug. 20, 1901). In penetrating wounds of the chest this complication can sometimes be readily seen or felt with the finger, at other times, prolapse of the intestines will give evidence of the condition. Often, however, the diagnosis is extremely difficult and can only be made by enlarging the wound. Symptoms directly traceable to the diaphragmatic injury, such as vomiting and changes on auscultation and percussion, are only exceptional. A knowledge of the character and length of the instrument used will often be of value. The importance of an operation is evident when we consider that the mortality in unoperated cases is 88 per cent. and in the operated only 12 per cent.

Influence of Water, Common Salt and Sodium Bicarbonate on Gastric Secretion.—By means of animal experimentation with gastric fistulæ, FRÉMONT (*Bull. therap.*, 1901, p. 575) showed that distilled water is capable of markedly stimulating gastric secretion; the temperature of water used is of comparatively little moment. Sodium chloride is said to be so mild a stimulant of the gastric mucous membrane that it cannot be relied upon to augment an insufficient secretion; bouillon is a more potent stimulant, and sodium bicarbonate causes the production of a voluminous viscid secretion.

Gas Cysts of the Central Nervous System.—Since the first description of gas cysts of the central nervous system, published in 1899 by Reuling and Herring and also by Howard, this subject has attracted considerable interest. W. T. HOWARD (*Jour. Med. Research*, July, 1901) now adds the study of six new cases. In five of these cases, proved to be caused by bacteria, four were due to bacillus ærogenes capsulatus and one to the bacillus mucosus capsulatus. In two cases of gas in the blood-vessels of the brain (and in

the disorganized brain tissue of one of them), associated with general gaseous emphysema, the first-named organism was present in pure culture in one and in association with the second-named organism in the other. He believes that frequent and more careful examination of the brain at autopsy, especially in cases of general emphysema, will probably show that gas cysts of this organ are more common than is generally supposed.

Albumosuria in Osteomalacia.—The appearance of the so-called Bence-Jones bodies in the urine has been considered as pathognomonic of multiple bone myelomata. G. JOCHMANN and O. SCHUMM *(Münch. med. Woch.,* Aug. 20, 1901) have, however, found the substance in a typical case of true osteomalacia, and by isolating it from the urine have proved that it belongs to the class of the albumoses. The diagnosis of osteomalacia was confirmed by microscopical examination.

Ptomain Paralysis.—The sudden appearance of motor paralysis in a boy of fifteen years and in his mother, aged forty, was attributed by P. A. PREOBRASCHENSKY *(Deut. Zeitschr. f. Nervenheilk.,* 16 Bd., 5. u. 6) to auto-intoxication of the gastro-intestinal type, due to eating fish. The clinical picture resembled a myasthenia or a polio-encephalomyelitis. There were no prodomata such as fever, vomiting or diarrhea. Almost all the muscles of the body were involved, but especially those supplied by cranial nerves, including the oscular muscles and those of speech, mastication and deglutition. The upper extremities were affected more than the lower; the paralysis developed in the course of several days, proceeding from above downward. There was no disturbance of sensation, of intellection, of bladder or rectum. A gradual return of muscular power occurred after several months.

Peritoneal Grafts of Echinococcus.—It has been shown that daughter-vesicles placed free in the peritoneal cavity are capable of forming attachments, of developing and of reproducing themselves. The liquid contents of the hydatid cyst alone are incapable of forming or of causing the production of a new cyst; they acquire this power only when they contain formed elements, either scolex or proligerous vesicles. Engrafted hydatid cysts rapidly acquire an endothelial covering and thus become secondarily extraperitoneal. The practical bearing of these facts is pointed out by M. GUIBÉ *(La Presse Méd.,* Aug. 28, 1901). They explain the occasional inoculation of the peritoneum in the course of surgical intervention. They constitute an argument against puncture in the treatment of hydatid cysts, for during or after puncture inoculation of the peritoneum may readily result from the escape of cyst-contents. They indicate clearly the most careful surgical treatment with as careful protection of the operative field as when an abdominal collection of pus is opened.

Action of Proteolytic Enzymes on Bacterial Toxins.—It is a well-estabished fact that many bacterial toxins when ingested by the mouth lose their toxicity. It is, however, not clear whether these toxins are neutralized by the enzymes or digested by them. This question is of fundamental importance in ascertaining the chemical nature of toxins for if these are simply neutralized they may be of a non-proteid composition, while if they are digested they are in all probability proteids. E. R. BALDWIN and P. A. LEVENE *(Jour. Med. Research,* July, 1901) have investigated this question in a series of studies in which they submitted toxins to the action of the proteolytic enzymes pepsin, trypsin and papain and subjected the resulting products to animal inoculation. They limited their researches to diphtheria and tetanus toxins and tuberculin. The first two are digested and not neutralized by each of these three enzymes. In regard to tuberculin the matter is more complicated. In a general way trypsin and pepsin digestion weaken the specific activity of tuberculin and trypsin on long action can destroy all its power while this result cannot be accomplished by pepsin. They hence feel justified in the conclusion that tuberculin is a nucleo-proteid, since these are more easily destroyed by trypsin than pepsin.

Protracted Influenzal Pneumonia in Infants.—While no period of life is exempt from influenza, it has been observed, during the pandemics of grippe that have encircled the world, that infants are in a high degree immune. Nevertheless four infants, suffering from protracted pneumonia of influenzal origin, were observed simultaneously in one institution, according to F. X. WALLS *(Jour. Amer. Med. Assoc.,* Aug. 31, 1901. In the presence of an influenza epidemic, with evident infection of other members of the household, the probability that a serious illness in an infant was influenza would suggest itself. The following diagnostic feature of grip pneumonia would be included: Sudden onset, mild intestinal symptoms, evidences of inflammation of the upper respiratory tract, sharp elevation of temperature and highly irregular course of fever, with physical signs of a lobar pneumonia and demonstration of Pfeiffer's bacillus. Prognosis should be guarded. The frequent occurrence of tuberculosis as a sequel should be kept in mind. Cases must be treated on general principles; so far as room-temperature is concerned, Walls recommends 80° to 85° F.—a temperature above that advised in ordinary pneumonias.

Indications for Gastric Surgery.—Concerning when to operate on the stomach, O. J. KAUFFMANN *(Birmingh. Med. Rev.,* Aug., 1901) expresses himself as follows: (1) Cases of perforation of the stomach which preclude that the general texture of the wall of the stomach is not greatly altered and that the perforation is small and recent are suitable. (2) For gastric ulcer with severe acute symptoms, even if recurrent, operation is inadvisable. (3) In atonic dyspepsia, if cancer is suspected but cannot be felt, the indication is so uncertain that rigorous diet, lavage, rest and medication should be given a thorough trial. (4) Where cancer is suspected, though not

palpable, and where anemia is beginning and progressing, exploratory laparotomy is advisable if the general condition permits. (5) Where cancer is improbable and where simple fibrous stricture or pyloric spasm is suspected, operation should be undertaken only if the weight falls progressively in spite of treatment.

Varieties of Diphtheria Bacilli.—The diagnosis of diphtheria by the examination of cultures necessitates the recognition of the bacillus by its microscopical appearance and the treatment and isolation largely depend upon the ability of the bacteriologist to so determine the presence or absence of this organism. Variability in form and staining reaction is one of the most striking characteristics of this bacillus. The questions arise, Can we identify this organism by its morphology alone? Is there a pseudodiphtheria bacillus? Has the susceptibility of the patient any influence upon the morphology of the organism? Is there any relation between the microscopical form and virulence? FREDERIC P. GORMAN *(Jour. Med. Research,* July, 1901) attempts to answer these questions by the means of experimental research. He examined 2,375 cases of which 431 showed diphtheria-like bacilli. The cultures were made on Loeffler's blood-serum, incubated for twelve to twenty-four hours, and the organisms were stained with Loefler's methylene blue. He confirms Westbrook's statement that the granular types are most predominant at the onset of the disease; but that they give place wholly or in part to barred or solid types shortly before their disappearance. Sometimes solid types may be replaced by granular types when convalescence is established shortly before the throat is cleared of this organism. The diphtheria-like organisms are more frequent in the nose than in the throat. There are diphtheria-like organisms present in the nares and throats of a large percentage of apparently healthy individuals. The change from granular or barred to solid types seems to take place under the influence of the body fluids of a person immune or becoming so. The virulence seems to be correlated with the morphology. So-called pseudodiphtheria bacilli are morphological varieties of the diphtheria bacillus and are sometimes capable of producing clinical diphtheria, but are not usually pathogenic for guinea-pigs. We cannot tell whether the solid types are able to regain their virulence when once they have lost it, but this seems probable. Neisser's stain is of no value in differentiating barred or solid types.

Psychoses of Influenza.—The various psychical disturbance having influenza as their cause may occur in persons hitherto of normal mental condition, says H. S. UPSON *(Cleveland Jour. of Med.,* Aug., 1901) when they usually take the form of delirium. Or the subjects may be more or less predisposed to nervous affections, when hallucinatory confusion, acute dementia, mania or melancholia is apt to follow. In the third class the insanity in some form is already in existence, but latent, and an exacerbation is evoked by the grip. Of the various deliria, the initial one is the most interesting in that it is often sudden and unexpected in onset and that it may appear with very mild attacks. Febrile and collapse deliria come later in the disease and are more common with the severer types. Acute hallucinatory insanity has strong points of resemblance with delirium on the one side and acute mania on the other and the hallucinations have a tendency to be of a horrific character. Acute mania and melancholia do not differ from those of other diseases; the same may be said of delirium tremens, which greatly enhances the danger of heart-failure. The general depression which follows grip deserves careful study and the languor, rheumatic pains and indefinite aches make rest almost intolerable. The prognosis in these psychoses is generally good, especially if the patients are not previously neuropathic.

Cardiac Lesions of Influenza.—It has been the experience of L. W. LADD *(Cleveland Jour. of Med.,* Aug., 1901) that next in importance to the pulmonary complications of influenza, the cardiac disturbances are to be rated. They frequently are purely neurotic in the form of tachycardia, bradycardia or arhythmia, but extreme cardiac failure and cardiac dilatation are not rare. The latter may be due to the action of the influenza toxin upon the nervous mechanism of the heart, it may be a true toxic myocarditis or dilatation may occur with conditions interfering with the outflow of blood. Ordinarily the dilatation is transitory and no permanent defect remains, but occasionally acute dilatation with sudden death supervenes. Pericarditis, while rare, is more frequent than endocarditis and in most cases pyogenic cocci have been found culturally. Acute aortitis has been reported several times.

Stenoses of Nose Affecting Distant Functions.—Several unusual cases are reported by W. P. PORCHER (*N. Y. Med. Jour.,* Aug. 31, 1901) showing how interference with the nasal passages may reflexly as well as directly affect the functions of the ear and throat. A small osteoma was removed from the septum of one case to relieve partial deafness for which no other cause could be found. The hearing was improved and a cough from which the patient had suffered for five years entirely disappeared. The removal of an hypertrophied turbinate bone in one case and a nasal polypus in another resulted in marked improvement of the sense of hearing in both cases. He quotes a number of good authorities to show what a close connection there is between the mucous membrane of the nose and the female genitalia. Several cases of marked dysmenorrhea have been entirely cured by cauterization of the four genital spots in the nose, and he suggests that in obscure cases of dysmenorrhea, purely neurotic cases due to reflex stimuli from the nose, may be separated from mechanical and organic obstructions to the menstrual flow by thoroughly cocainization of these genital points during an attack and observing the results.

Yellow Fever in Havana.—During the last three years only, there has been an accurate ac-

count of the number of cases of yellow fever in Cuba, but the disease has been about equally prevalent each year and very little progress had been made against it until more sanitary methods were introduced by the Americans. W. C. GORGAS (*Med. Rec.*, Sept. 7, 1901) gives a history of the disease in that locality, showing that it begins to appear soon after the first of April and slowly increases until it reaches its height in July and then decreases during the fall and winter. During the last three years the number of deaths has much decreased and only two have occurred thus far this year. The methods of sanitation are founded upon the belief that the mosquito is responsible for conveying the disease and every effort is made to destroy favorable breeding-places for these insects. The city is closely inspected, all cesspools drained, and no stagnant water is allowed to stand unless protected by mosquito-proof netting. Coal oil is used freely upon all water which cannot be drained away, and the results which have attended the efforts made are most satisfactory and encouraging.

Conservatism in Pelvic Inflammations.—In conducting a series of microscopical examinations of the Fallopian tubes removed by operation, J. L. ROTHROCK (*St. Paul Med. Jour.*, September, 1901) was struck by the slight changes which had occurred in these structures. He advances a plea for greater conservatism in such conditions. Many attacks of pelvic inflammation do not reach the stage of suppuration. Indeed, at the Leipsig Frauenklinik, but 4 per cent. of all the cases terminated thus. In patients operated on there was a relief of symptoms in only 33 per cent., while the remainder underwent the same sufferings after as before the operation. Even in the so-called successful ones, the neurotic tendencies superinduced by the removal of the ovaries became sources of grave danger. The author therefore experimented upon a great many cases in his practice with a view of determining the necessity or otherwise of radical operation. His treatment consisted chiefly of local measures. After removing the mucopurulent secretion from the cervix, daily irrigation of the uterine cavity is practised with bichloride of mercury, 1-5000, or with permanganate of potash, 1-1000, following with an application of ichthyol, 50 per cent., in glycerin; or formalin 25 per cent. Should the os be stenosed which often happens in multiparæ, the cervix must first be dilated. It is absolutely necessary that the os should be patulous in order to secure free drainage. In cases where localized peritonitis is present, the patient is first placed in bed, an absolute rest is essential. Cold or hot applications to the abdomen and antiseptic douches are at this stage the only treatment. After subsidence of all pain and fever local treatment is begun. The duration of such local treatment embraces a period of from six to eight weeks. In cases in which the early treatment has been neglected, the outlook is not so encouraging. Should pus have accumulated, drainage *per vaginam* is much safer than the other route. It may be remarked that Kroenig of Leipsig has stated that in 90 per cent. of his cases, treated by the expectant method, the results were so favorable that subsequent treatment was unnecessary.

A New Continued Fever.—An epidemic of about sixty cases of a disease manifesting itself by a rapid onset, chilly sensations, increasing temperature, irregular pains and mental depression has been reported by E. J. SPRATLING of Georgia (*Med. Rec.*, Sept. 7, 1901). The temperature frequently ran up to 104 to 106°F. It resembled dengue in many particulars, but was too variable in its mode of onset. In dengue whole families are usually affected; in this, rarely more than one. The symptoms lasted only from two to five days and then rapidly subsided. The patients would "feel fine" afterward and "could get up if only stronger." The erratic fever usually persisted for three to five days longer. Prognosis was good when the heart was not affected. The author believes this to be a close congener of, if not actually, Mediterranean fever.

Menthol in Gastritis.—The uses of menthol in acid dyspepsia are described by G. E. CAMPBELL (*St. Paul Med. Jour., Sept.*, VIJV). He used the drug in stomach troubles characterized by gastrodynia, distention, eructation, cardiac distress and vomiting. The object in these cases is to neutralize the hyperacidity and relieve the hypersensitiveness of the organ. The author uses for this purpose menthol combined with bicarbonate of sodium before meals and pepsin after meals. Menthol given in ⅛- to 2-grain doses one-half hour before meals relieves the distressing pain, and has given by far the best results in these cases.

The Influence of Auditory Lesions on Galvanic Vertigo.—If the electrodes of a galvanic current be applied to opposite sides of the head the subject becomes dizzy; the head and upper part of the trunk incline toward the side to which the anode is applied. According to J. BABINSKI (*Soc. de Biol.*, 1901, No. 4) the inclination of the head produced by the galvanic current is, in cases of ear trouble, toward the diseased side. Babinski regards the vertigo which occurs as the effect of electrical stimulation of the labyrinth. His observation is of possible value in fixing the diagnosis of doubtful cases of ear disease with involvement of the labyrinth.

The Specific Treatment of Tabes.—A protest against the introduction of a rigorous antisyphilitic regimen in all cases of tabes, regardless of the individual history, is made by K. v. KETLY (*Orvosi Hetilap.*, No. 2, 1901). In the presence of other evidences of syphilis, antiluetic treatment should be begun at once; but where there are no other signs of an active syphilitic infection and the etiology is based on historical data, mercury should only be resorted to provided the tabes is in its early stage and the patient is in good condition. In advanced tabes the weak-

ness of the patient is intensified by specific treatment. In early cases where syphilis is merely suspected, specific treatment may be tried, but should be discontinued if it proves ineffectual or if troublesome symptoms arise. Tabes itself, according to this writer, is not cured nor directly affected by mercury. Our efforts should be directed toward increasing the vital resistance of the organism, and toward modifying symptoms. Patients must avoid physical and mental strain, exposure to cold, excesses *in Venere* and *in Baccho*. Moderate exercise is advisable. Internally v. Kétly recommends silver nitrate in pills. In syphilitic neuralgia potassium iodide is invaluable. Faradization and galvanization, and hydrotherapy, are useful factors in treatment.

THERAPEUTIC HINTS.

Measles.—Confine patient to bed in room at 65° F. and if cough is hard and irritating have a croup-kettle to keep the air moist. The diet may be milk diluted with barley-water or seltzer or in mild cases sops or light puddings may be allowed. Frequent spongings with warm water containing tar-water relieve the itching and tend to bring out the rash. Demulcent drinks, such as barley-water, lemonade, black-currant or tamarind drinks or jellies will allay irritating cough. During the pre-eruptive stage, with high fever, restlessness, cough and frequent pulse, small doses of tincture of aconite will give relief. During convalescence great care should be taken to prevent catching cold, as such a complication may produce serious results. When there is scant rash, congestion of internal organs, high temperature and bronchopneumonia, the skin must be made to work actively by tepid sponging, hot packs, or mustard baths. A child under two years may be placed for three minutes in a bath at 100° F., containing one tablespoonful of mustard to a gallon. In older children, the hot pack is preferable. In the early stages tartrated antimony, gm. 0.0005-0.001 (gr. $^1/_{120}$-$^1/_{60}$), with tartrated soda or citrate of ammonium, should be given every three or four hours unless there be nausea; whisky or brandy should be given if the pulse is small and rapid, or the tongue brown and dry. Excessive bronchial secretion requires ammonia, digitalis and alcohol. In severe cases the eyes, nose and mouth should be bathed in warm water and carefully looked after. During convalescence no medicine answers better than nitric acid and bark.—ASHBY and WRIGHT in "Diseases of Children."

Hot Air.—Although moist temperatures of 125° to 150° F. cause a distinct burning of tissues, and are bearable for a short time only, nevertheless the same temperature free from moisture, writes O. S. WIGHTMAN (*N. Y. Med. Jour.*, Aug. 17, 1901), may not only be borne with comfort, but with positive sensations of relief. The part to be baked, having been washed and thoroughly dried, is wrapped in soft absorbent material which will absorb the moisture that collects on the surface. Light blankets, rough toweling or heavy cotton-batting may be used. The part is then placed in the oven. If in pain the first sensation is that of needles pricking, but this soon gives way to a feeling of comfort. The physiological action of dry heat consists of a rapid dilatation of the peripheral arterioles, followed by flushing or mottling. In the heavy parts there is a local stimulation of glandular secretion. In sluggish ulcers, cell-growth is stimulated. The heart's beat increases from ten to twenty-five a minute and the respiration from two to six. The kidneys are much relieved of congestion, though immediately after treatment there may be a decrease of fluid and solid constituents in the urine. After an hour's exposure, the mouth temperature rises from two to five degrees. Of the nerves, there is primary stimulation of the vasoconstrictors, then of vasodilators, and, finally, a desire to sleep. The cases suitable for treatment are sprains, synovitis, contusions, traumatic inflammations, edema following fractures, acute and chronic nephritis, anasarca, dropsy, and, above all, gout and rheumatism. Other diseases reported as benefited are suppressed menstruation, pleurisy, bronchitis, ulcers, skin lesions, and various neuroses. In connection with heat, too much stress cannot be laid on the value of massage, except in acute inflammations, and in all cases constitutional treatment should not be neglected. The advantages, then, of dry heat are as follows: It relieves pain without depressant effects, stimulates rapid repair, absorption, and elimination, and acts as a sedative to the nervous system beyond every other agent.

Gelatin in Hemorrhage.—The use of circulatory stimulants and vaso-constricting styptics, such as ergot or suprarenal extract, to check internal hemmorrhage, is directly opposed to Nature, writes H. C. WOOD, Jr. (*Merck's Archives,* Aug., 1901). Gelatin is practically insoluble in cold water, but freely in hot, and if over 2 per cent. it solidifies on cooling. If the solution is maintained at a temperature above 110° C. (230° F.) it loses the property of jellying. Weak salines cause comparatively little change in the jellification. A five-per-cent. solution of gelatin in physiological salt solution made the urine of a dog solidify on cooling, and the blood from the dog coagulated almost instantly, the coagulation being a true clot, and not a jelly. In studying anti-coagulants, gelatin was successful in making the blood clot only in the presence of peptone anti-coagulants, as propeptone. As a local stypic, in menorrhagia and metrorrhagia, hematemis from gastric ulcer, hemorrhoids, etc., it has proven of great value. But as an internal remedy in hematuria, hemoptysis, purpura hæmorrhagica, hemorrhage following operations on the icteric, etc., it has also been found to have a value possessed by no other drug. The total amount injected should be from gm. 1-5 (gr. xv-lxxv). Locally it is used in 10-per-cent. solution.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, SEPTEMBER 21, 1901.

THE PRESIDENT'S CASE.

PRESIDENT MCKINLEY died at two o'clock on the morning of Saturday, September 14th, seven and a half days after his injury was received. Up to and including most of Thursday, the sixth day after the injury, he had apparently been advancing steadily toward recovery; his temperature had fallen below 100° F., his abdomen was soft and painless and he had taken liquid food by the mouth with relish, but his pulse remained at a little above 120, and on Tuesday some of the stitches had been removed from the incision for the relief, as stated, of a slight infection thought to have been caused by a piece of the shirt carried into the wound by the bullet. His recovery was predicted by those in attendance and by many other physicians interviewed by the papers in various parts of the country, and the prediction seemed amply justified because he had passed the period during which the habitual causes of death after such an injury and operation manifest themselves.

But on Thursday a notable weakness of the heart appeared; it was thought to be due to indigestion, and a laxative was given. Early in the morning of Friday the weakness recurred in an alarming way and persisted, with some intervals of slight improvement under stimulation, until his death twenty-four hours later. Death came quietly after six hours of unconsciousness.

A brief official note of the autopsy, made nine hours after death, was promptly published, and has been followed by informal but apparently authorized statements giving additional details by some of the attending surgeons.

The official account of the autopsy is as follows:

"The bullet which struck over the breastbone did not pass through the skin and did little harm. The other bullet passed through both walls of the stomach near its lower border. Both holes were found to be perfectly closed by the stitches, but the tissue around each hole had become gangrenous. After passing through the stomach, the bullet passed into the back wall of the abdomen, hitting and tearing the upper end of the kidney. This portion of the bullet track was also gangrenous, the gangrene involving the pancreas. The bullet has not yet been found. There was no sign of peritonitis or disease of other organs. The heart walls were very thin. There was no evidence of any attempt at repair by Nature, and death resulted from the gangrene, which affected the stomach around the bullet wounds, as well as the tissues around the further course of the bullet. Death was unavoidable by any surgical or medical treatment and was the direct result of the bullet wound."

The unofficial statements are somewhat conflicting as to matters of fact and opinion. Dr. Wasdin is reported as saying:

"I have seen many gangrenous cases, but none in which the parts lacerated by the bullet were so completely and uniformly affected. The entire tract of the wound from the outer surface of the abdomen, through the tissue, fat, stomach, and abdominal cavity back of the stomach was thoroughly and completely gangrened.

"The wound in the posterior wall of the stomach was particularly affected, the gangrene extending for a radius of almost two inches around the sutures.

"I have never seen such a condition. When the stomach was removed the tissue bore no resemblance to human tissue, and, in fact, was as bloodless as, and much resembled, a piece of clay.

"On Tuesday it was decided to open the external wound in the abdomen. There had been some irritation there, and we decided to find out the cause. At first we took out a few of the stitches and, later, laid open the entire incision, leaving an opening in this wound five inches long and three inches deep. It required no effort to open the incision. We immediately found in the track of the bullet through the flesh and fatty tissue that gangrene had developed. None of the parts other than those around the immediate

bullet wound were affected. We removed this affected tissue, cleansed the wound and closed it."

Dr. Wasdin attributed the gangrene to "some powerfully corrosive poison" introduced upon the bullet, and added: "My belief that the bullets were poisoned is strengthened by the fact that the wound in the breast, although very slight, had gangrened when the autopsy was performed."

Dr. Park, in an interview said to have been written out in his presence, says:

"There is no reason to believe that poison was introduced into the wounds. The gangrene was caused by the secretion of the pancreas escaping from the wound and producing the trouble. The pancreas was perforated by the bullet. There was no way in which we could determine from outward evidences that gangrene had set in. There are no indicative symptoms."

"Is it not a fact, Doctor, that when the surface wounds were opened Tuesday it was found to be affected by gangrene, and that the affected portions were then removed?"

"No, Sir; it is not. There was merely an irritation, and we found nothing that indicated the presence of gangrene. Even at the autopsy it was discovered that gangrene existed only along the track of the bullet from the posterior wall of the stomach to the kidneys. The wound in the anterior wall of the stomach was but very slightly affected."

Dr. Mann says:

"No. The only parts in the abdominal cavity penetrated or touched by the bullet were the stomach walls and the top of the kidney. The pancreas was not touched, although it was involved in the gangrenous process. I was surprised, in fact astounded, at the condition of the internal organs revealed by the autopsy. In all my experience I have never found organs in such a state; to use a vulgar phrase, they were rotten."

Dr. Mynter says that the pancreas was not wounded and that no gangrene was observed along the course of the bullet through the anterior abdominal wall when the incision was opened on Tuesday. Both he and Dr. Mann declare themselves unable to account for the extensive gangrene.

Of these differences as to matters of fact, the one concerning the presence of gangrene in the parietal incision may be dismissed as simply due to a difference of definition. Something must have been wrong there, or the sutures would not have been removed. Whether that was an "irritation," as Dr. Park calls it, or a superficial necrosis along the track of the bullet, it could not have affected the result, and its sole significance is in its possible bearing upon the cause of the extensive gangrene observed elsewhere.

Much the same can be said of the asserted and denied wounding of the pancreas. It is asserted by one, denied by three, and not mentioned in the formal report. Probably, therefore, it did not exist or was slight.

There remains the extensive gangrene, which is affirmed by all and which was undoubtedly the cause of death, and the question of its origin. Two theories have been advanced, (1) that it was due to a poison conveyed by the bullet, and (2) that it was due to the action of pancreatic juice that had escaped from the wounded gland. The second theory seems untenable because similar action is not described as occurring after other wounds involving an escape of the pancreatic juice, because the gangrene involved parts (the anterior wall of the stomach), which the escaping juice could not have reached except after having passed by other parts which were not similarly affected and because it appears to have been a necrosis, a death in bulk, rather than a progressive digestion. And this view is reinforced by the fact that as the patient had been fed for the first four days exclusively by the rectum, the pancreas had not been stimulated to functional activity.

The other theory, that of a poisoned bullet, is warmly urged by Dr. Wasdin. In the absence of specific proof, such as may yet be furnished by bacteriological or chemical tests of the tissues and of the other bullets, it seems as unlikely to be correct as the other. The author of the theory admits his inability to name a poison that would produce such an effect, and the two poisons recommended in the Anarchist manual of assassination, curari and verdigris, are incompetent to produce it. We must therefore await the results of the investigation said to be now in progress. If sloughing existed, as asserted by Dr. Wasdin, beneath the unbroken skin of the breast, where it was struck by the other bullet, it cannot be explained by either theory.

The gangrene, extensive as it was, seems to us not so different from others observed under analogous circumstances as to require the assumption of exceptional causes for its explanation. Necrosis of tissue in a thinner or thicker cylinder along the track of a bullet is thought to be the rule, and ordinarily it is easily taken care of by liquefaction and ab-

sorption. And necrosis, even of considerable extent, in feeble patients, about a sutured wound is certainly not unknown even if rare, and is explained by interference with the local circulation either by tension or by the spread of coagulation within the blood-vessels. It has not been made known to us whether this was a septic or an aseptic necrosis, but it was presumably septic, since the parietal wound presented symptoms, due apparently to the same process at that point, which necessitated the removal of the sutures.

In either case, and especially in the former, the spread of the process in a patient of low reparative power would not be so very exceptional or surprising. Was the President such a patient? Apparently he was. According to Dr. Wasdin, when the incision was reopened toward the end of the fifth day "no effort" was required to open it throughout its entire length, although only the track of the bullet was affected. That expression would hardly have been used unless he had intended to indicate that the amount of repair usual after that lapse of time had not taken place. Then, the President was fifty-eight years of age, had led a sedentary, laborious, and anxious life, and had a complexion and appearance which for some years had been commented upon as indicative of impaired vitality.

It is evident that the surgeons, notably Drs. Mann and Mynter, with whom the first decision lay, acted with commendable promptitude and courage in undertaking the operation, and showed excellent judgment in its course and skill in its execution. They did all that could properly have been done and nothing that should have been left undone. The usual causes of death after such injury and operation were escaped or removed or prevented, and their patient succumbed to a complication which is so rare that it could not reasonably have been anticipated and could not have been averted. The President died because he could not carry on the processes of repair, and because the effort to do so was more than the vitality of the tissues involved could support. This, of course, excludes the possible presence of poison brought by the bullet or of destructive action by the pancreatic juices. If either of those was a factor, it needs only to substitute it in the statement for the assumed defective vitality of the patient. Whatever cause acted, it was unrecognizable at the operation and uncontrollable then or subsequently.

There has been some criticism of the confident assurances of recovery made by those in attendance after the fifth day. To us the progress of the case up to that time appears fully to have justified those assurances and the public anxiety to have required them. The habitual causes of death had been escaped, and recovery could be prevented only by some rare complication which there was no reason to anticipate. The only irregular symptom was the frequency of the pulse, and that could be reasonably accounted for without invoking conditions that endangered life. There was not the slightest nausea, no complaint of discomfort, not the least abdominal pain; a soft abdomen in which percussion and firm pressure disclosed no sensitiveness; the bowels acting; the tongue clearing; the temperature falling; and a cheerful mind. Who can think that with such conditions on the sixth day the surgeons were not fully justified in believing that recovery was assured and, believing, in saying so? That a rare and at that time wholly unindicated complication should have then intervened was their and our misfortune. They did their work skilfully and judiciously, their behavior was dignified, restrained, and worthy of the best traditions of the profession, and they had the misfortune, when success seemed to have been secured, of seeing it overthrown by a complication which could not have been foreseen or avoided. They deserve our admiration and sympathy, not our criticism.

MEDICAL RESEARCH AND REGULATION IN THE PHILIPPINES.

THE United States Government has recognized the needs of medical research in the tropics and the advantage of a health department for the protection of its citizens. It has therefore created two institutions meant to fill these wants, a Government laboratory and a board of health.

Under the term of the Government laboratory there is to be a biological laboratory, a chemical laboratory, and laboratories for the production of vaccine virus and of serums and prophylactics will be established and maintained by the Government of the Philippine Islands. The biological laboratory will be situated at Manila, and will afford adequate facilities for investigation into, and scientific report upon, the causes, pathology,

and methods of diagnosing and combating the diseases of man and of domesticated animals, and of animals utilized for food, and of plants useful to man, as well as for such other biological work as may be deemed necessary by the Board of Health for the Philippine Islands, the Forestry Bureau, the Bureau of Agriculture, or any other department or bureau of the Government.

The chemical laboratory will be situated at Manila, and will afford adequate facilities for investigation and report as to the purity of foods and drinks; as to the composition and properties of gums, resins, drugs, herbs, or other plant products of known or supposed commercial value; as to soils or fertilizers; as to minerals and minero-medicinal waters of the Philippine Islands, and for such other chemical investigation as may be deemed necessary by the Board of Health for the Philippine Islands, the Department of Public Instruction, the Forestry Bureau, the Mining Bureau, the Bureau of Agriculture, the Customs Service, or any other department or bureau of the Government.

Laboratories for the production of vaccine virus and of serums and prophylactics will be established and maintained at Manila and at such other points in the archipelago as the Board of Health for the Philippine Islands may advise and the central legislative body of the Islands may determine upon.

There will be a superintendent of government laboratories, at a salary of $4,000 per year. He will have charge of the construction and equipment of all Government laboratories for the Philippine Islands and of the purchase of all apparatus, supplies, and books which may be authorized for use in connection with such laboratories.

With such an ample provision it is evident that some valuable results can be obtained. We further congratulate the Government in its choice of the Superintendent, Dr. Freer of Ann Arbor.

The Insular Board of Health is also founded on broad lines and has had conferred upon it the powers of a modern municipal health department.

SUCCESSFUL PHOTOTHERAPY.

THE recent award to Prof. Finsen of Copenhagen of one of the magnificent Nobel prizes (its value is over $50,000), established by the will of the great Danish manufacturer of dynamite, recalls the attention of the medical world to Finsen's successful researches in the domain of light therapeutics. It is fortunate, for in the multitude of claims on medical attention, sometimes the really good things are for a time at least crowded out of sight. Prof. Finsen's work, accomplished with patient scientific carefulness and modestly given to the medical world with none of that blare of trumpets that has so often of late accompanied less deserving and successful effort, fully merits the reward and the renewed attention that will be given to it as a consequence.

Prof. Finsen's researches into the effect of light on human beings began with the investigation of the influence of light in smallpox. Only parts of the body, as the face and hands, that are exposed to the action of light during the course of the disease become disfiguringly pitted by smallpox. All the methods of treatment suggested for smallpox, before Finsen's investigations, that had any measure of success in the prevention of pitting had this in common—they kept the hands and face of the patient more or less thoroughly protected from light. This was accomplished in various ways, mostly without any direct intention of light occlusion on the part of the inventors, but, fulfiling this purpose unfailingly. Prof. Finsen then protected a series of smallpox cases from the light and showed that this method of treatment sufficed in practically every case in which it was begun sufficiently early in the disease to suppress the secondary suppurative stage of the disease and consequently to prevent all danger of pitting. It is almost needless to say that it is the secondary fever of smallpox which constitutes the most serious period of the disease. It is at this time that the vast majority of the deaths from the disease take place and that consequently Prof. Finsen's treatment, far from being only cosmetic in its effects, saves many lives and much suffering.

Finsen was thus encouraged to investigate further into the action of light upon the skin. He found that the harmful effects of light were all due to the rays from the violet end of the spectrum. The light rays that affect a photographic plate, some of them beyond the violet in the spectrum, and so producing no sensation of light for human vision, are also active factors in the production of irritative skin conditions. For the successful treatment of smallpox cases it was only necessary, then, to exclude the violet and related rays of light by means of dark-red glass. This discovery has been confirmed by many observers and especially in our present smallpox conditions deserves more serious attention.

Finsen's researches were appreciated by his fellow-countrymen better than is usually the case. He was enabled to continue his investigations into the possibilities of preventing the harmful action of light in disease and using it as a direct therapeutic agent by the generous erection for him of a Light Institute in Copenhagen. He knew that light was a bactericide. His investigations in smallpox showed that the action of light penetrated well beneath the superficial layers of the skin. In variola the light injured the cutaneous cells more than it did the microbic cause of the disease, but it might well prove that in other diseases, the bacteria would be destroyed without serious injury to the skin. Finsen tried the action of concentrated light upon lupus patients and found that it produced a cutaneous reaction that was followed by the cicatrization of the lupus nodules. He continued his observations for several years and convinced himself of the absolute certainty of his results before he gave his conclusions to the public. His communication was considered to be one of the most valuable practical contributions to dermatology in the last decade of the century.

Finsen experimented with the action of light in other diseases, but without as much success as in lupus vulgaris. Lupus erythematosus was sometimes favorably influenced by phototherapy, but sometimes it was not. If the disease is due, as is thought by many, to the toxin of tuberculosis in contradistinction to its congener lupus vulgaris, which is the result of the presence of tubercle bacilli, then the difference in the effect of light on the two diseases would seem to point to a true parasiticidal action of light in the therapy of lupus vulgaris. This is confirmed by the fact that alopecia areata is always favorably influenced by exposure to concentrated light, for this disease is now very generally considered to be due to the presence of a parasite.

In recent investigations Prof. Finsen has shown conclusively that light, apart from heat, is capable of producing effects in the skin that persist for long periods. Exposure of the arm for twenty minutes to the light of a 40,000 candle-power electric light (the large arc light used for lighting city parks and squares is, according to Prof. Finsen, never of more than 4,000 candle-power) is followed by a severe inflammatory reaction and then by pigmentation that persists for many months. Finsen's patient, modest, successful work deserves the reward that has come to him all unsought. The monetary part of it will doubtless be well employed in furthering the progress of phototherapy. He has gathered around him a band of younger workers who have caught some of his enthusiasm. A recent volume of the Transactions of the Finsen Medicinske Lysinstitut (Medical Light-Institute) gives promise that this new and encouraging branch of therapeutics will receive the due share of careful experimentation that will guarantee its timely development to the fullest possible extent.

SECRET MEDICINAL PREPARATIONS.

AMONG the points in the administration of public affairs in the Old World which claim our admiration is the official control exercised over medical matters. A report of the United States Consul-General at Vienna shows the measures adopted by Austria for the protection of the people of that country. The sale of secret remedies is forbidden and no apothecary is permitted to keep for this purpose any medicinal preparation "of which the prescription is not open to inspection by physicians or in the prescription of which the substance of the medicinal ingredients cannot be definitely recognized as to kind and quantity." Government inspection of all new preparations is required before their sale is allowed, and cosmetics the labels, wrappers, or advertisements of which claim that they are efficacious in removing personal blemishes are absolutely barred. No testimonials from abroad of the cures effected by patent remedies may be published in the local papers.

The wisdom of much official regulations cannot be questioned. It is more than doubtful, however, whether the needful legislation could be secured in this land, where the privilege of being humbugged is claimed as one of the inalienable rights of the citizen of a free country, and where opposition to the acts of others is attributed to jealousy on the part of the medical fraternity. Does not Mark Twain, attempting to depart from the field of humor in which he is frequently successful, complain, "How is it that there are a thousand ways in which I may be permitted to damn my soul, but when it comes to a trivial matter like temporary ill health, the Legislature must prescribe how I shall do it. It is absurd and ridiculous?" The almighty dollar and political ambition are still more serious obstacles. The stand of the powder and shot manufacturers in the crusade against the butchery of thousands of living pigeons in the name of sport illustrates

the difficulty in obtaining legislation which affects the pockets of a large and wealthy class.

And what an outrage to restrict the publication of testimonials—the only means short of violent crime that many prominent citizens of Wayback possess for obtaining publicity! The depth of such an injury is too great to be lightly passed over. There is apparently but one honor which touches a certain type of citizen of uncertain degree of education as keenly as he feels the privilege of being humbugged, and that is the publication of his portrait, name, and an alleged personal testimonial. It is related that a stranger recently approached a man of national prominence and said that he believed he had seen his picture somewhere. Being told that it was quite possible, he asked, "What were you cured of?" The life of the reformer is hard, and the introduction of the ways of monarchies is not considered by Mr. Spate to be easy or a complete success. Public restriction of secret medicinal preparations is almost too much to expect in the near future.

ECHOES AND NEWS.

NEW YORK.

Board of Health Asks More Money.—The Department of Health of New York City has submitted to the Board of Estimate and Apportionment its estimate of the amount necessary for the coming year. While last year $1,053,990 was allowed by the Board, this year an increase of $346,266 is asked for, making a total of $1,410,256.

Summer Milk Depots' Work.—All the regular summer depots of the Nathan Straus sterilized milk charity in New York City close this week. The present season has made greater demands upon the work than any of the preceding nine years of its existence and a greater quantity of milk has been dispensed. There were thirteen depots open during the season, all situated in the poorer districts of the city, where the need was greatest. There were distributed 770,700 bottles of milk. Besides the bottled milk, more than one million glasses were drunk in the different booths. During the entire winter four depots will remain open.

New French Hospital.—The French Benevolent Society has awarded the contract for the new hospital of the society, which is to be built upon the recently acquired property on Thirty-fourth street, between Ninth and Tenth avenues. The building will be of seven stories, and provide accommodations for one hundred and fifty patients and attendants, besides offices for the association. The society was incorporated in 1819, and the hospital was founded in 1881. It is a non-sectarian institution, and receives no aid from the State.

School for Crippled Children.—The free school for crippled children, 434 West Fifty-seventh street, opened on Monday last with an attendance of forty-six children, the full capacity of the school. Ten of these children are perfectly helpless, but they are brought to and from the school with the others in a wagonette provided by the Woman's Auxiliary to the Guild for Crippled Children of the Poor.

Appointment of Dr. Fischlowitz.—Dr. Gustav G. Fischlowitz has been appointed assistant attending surgeon to the New York Maternity Hospital.

Medical Society of the State of New York.—The Medical Society of the State of New York will hold a semi-annual meeting in Hosack Hall, New York Academy of Medicine, No. 17 West 43d street, New York City, on October 15 and 16, 1901. The titles of papers to be presented are announced as follows: A Contribution to the Pathogenesis of Narcolepsy and other Forms of Morbid Sleepiness, by Heinrich Stern, New York; The Dyspeptic Heart, by James K. Crook, New York; The Official Relation of the Medical Profession to Private Charitable Institution, by Enoch V. Stoddard, Rochester; Cerebral Apoplexy, by Edward D. Fisher, New York; The Causes and Treatment of Epilepsy, by W. P. Spratling Sonyea; Hallucinations: Their Pathogenesis, Clinical Import and Medico-Legal Value, by J. Leonard Corning, NewYork; Note on the Refinement of the Technic of Spinal Anesthesia, by J. Leonard Corning, New York; Tropacocaine in Spinal Anesthesia, by Willy Meyer, New York; Therapeutics and the Drug Manufacturer, by B. W. Loomis, Syracuse; Prolonged Medication, by A. Jacobi, New York; Muscular Atony as the Principal Factor in Uterine Displacements, by Henry C. Coe, New York; A Brief outline of the Surgical Procedure in Tubal Pregnancy, with Report of Case, by H. T. Williams, Rochester; The Treatment of Chronic Endometritis, by Hermann J. Boldt, New York; Some Facts and Fallacies Concerning Pulmonary Tuberculosis, by John H. Pryor, Buffalo; Notes on the Early Diagnosis and Treatment of Pulmonary Tuberculosis, by J. Elwood Stubbert, Liberty; The Association of Pulmonary Tuberculosis with Cardiac Lesions, by J. M. Anders, Philadelphia; Dysmenorrhea, by Matthew D. Mann, Buffalo; Cancer of the Uterus, by William R. Pryor, New York; Abdominal Actinomycosis, with Illustrations and Report of a Case, by Albert Vander Veer, Albany; Old Age as a Factor in the Cure of Hernia, by W. B. De Garmo, New York; Problems in the Management of Tubercular Disease of the Hip, Based upon Records in Private Practice, by Virgil P. Gibney, New York; Mechanical and Oper-

ative Treatment of Hip Disease, and Disease of the Spinal Vertebræ, by A. M. Phelps, New York; The Difficulties Encountered by the Sanitarian in Dealing with Smallpox, by Ernest Wende, Buffalo; The Clinical Symptoms of Advanced Cardiac Disease, of Cases in which the Right Heart is Relatively Most at Fault, by Louis F. Bishop, New York; The Advantages of Stereoscopic Radiography, by L. A. Wiegel, Rochester.

Symposium On Some of the Diseases of the Liver and Bile-Passages: The Diagnosis of Gall-Stones and their Aberrances, by Charles G. Stockton, Buffalo; Courvoisier's Law, by Richard C. Cabot, Boston; The Infections of the Gall-Bladder and Bile-Ducts, M. H. Richardson, Boston; Intestinal Obstruction due to Gall-Stones, L. S. Pilcher, Brooklyn; Technic of Gall-Bladder and Duct Operations, by S. J. Mixter, Boston; Cholecystectomy, by C. L. Gibson, New York; Syphilis of the Liver, by Simon Flexner, Philadelphia; Tumors of the Liver, by G. R. Fowler, Brooklyn.

The Physiological and Clinical Action of Normal Salt Solution, with Indications for Its Use, by W. H. Heath, Buffalo; Medical Aspect of Appendicitis, by N. E. Ford, Utica; Aspiration of Wire Nail, Gangrene, Septic Pneumonia, by Francis Huber, New York; The Etiologic Potency of Heredity in Mental Disease, by Carlos F. MacDonald, New York; The Pathology and Treatment of Migraine, by William H. Thomson, New York; A Few Urinalysis Deductions, by Hamilton D. Wev. Elmira; Method of Incising, Searching and Suturing the Kidney for Stone, by Howard A. Kelly, Baltimore; The Technic of Nephropexy, by Geo. M. Edebohls, New York; Morcellement and Bisection of the Uterus in Complicated Abdominal Hysterectomy, by Willis G. Macdonald, Albany; The Immediate Repair of Injuries of Parturition, by A. L. Beahan, Canandaigua; A Smallpox Epidemic in an Orphanage, by Frederick C. Curtis and H. L. K. Shaw, Albany; Report of a Case of Non-traumatic Perinephritic Hemorrhage, by Arthur Booth, Elmira; Are the Tonsils to be Regarded as One of the Normal Organs of the Body, by F. H. Bosworth, New York; The Early Diagnosis and Treatment of Acute Mastoiditis, by T. H. Halstead, Syracuse; History and Presentation of a Case of Cerebral Abscess Complicating Chronic Otitis Media, by Robert Lewis, Jr., New York; Some Conditions Antecedent to Cancer of the Breast, by B. F. Curtis, New York; Ligation of the Abdominal Aorta for Aneurism, by Robert T. Morris, New York; Observations on the Treatment of Croupous Pneumonia, by J. C. Wilson, Philadelphia; The Clinical Evidence of Myocardial Conditions, by John L. Heffron, Syracuse; A Case of Intermittent Claudication, Terminating in Gangrene, by I. N. Levry, Syracuse; The Present Status of Ophthalmic Science and Art, by D. B. St. John Roosa, New York; The Beneficial Effect on the Eyes from the Use of the Stereoscope, by A. Edward Davis, New York; Glaucoma Simplex and its Treatment, by Peter A. Callan, New York; The Evolution of Typhoid Fever Theories, by Richard Stein, New York.

CHICAGO.

Death-Rate of Children Lower.—The weekly bulletin of the Health Department of Chicago says that there were 483 deaths during the week ended September 7, 1901, this being 32 fewer than during the preceding week, but an excess of 39 as compared with the corresponding period last year. The reduction in the week's mortality, as compared with the week preceding, is due principally to the lower mortality among children under five years of age, the reduction at this division being chiefly attributed to fewer deaths from the acute intestinal diseases, diphtheria, convulsions and infantile marasmus. The continuance of the remarkably low mortality from diphtheria which has prevailed during the Summer months still holds good, there having been but four deaths recorded as due to this disease during the week. With the re-opening of the public schools, however, there has in times past been a marked increase in the contagious disease mortality, especially diphtheria.

Testimonial Banquet to Dr. N. S. Davis, Sr.—The medical profession of Chicago will tender to Dr. N. S. Davis, Sr., the father of the American Medical Association, a testimonial banquet October 5th. Several prominent members of the profession from the outside have been invited to attend, and to make speeches at the dinner, and among them Drs. William Osler, Victor C. Vaughan and John A. Wyeth.

Sterilization of Pencils.—Health Commissioner Reynolds has recommended the sterilization of pencils used in the public schools, and Superintendent Cooley has been asked to submit the matter to the Board of Education. Pencils are distributed at every session and the children habitually put them in their mouths.

Changes at Baptist Hospital.—On account of the resignation of Dr. Reuben Peterson, of the staff of physicians, Dr. Palmer Singley was appointed to fill his place. Dr. Peterson is leaving in order to accept a position at Ann Arbor. Dr. A. E. Halstead and Dr. C. E. Paddock were also appointed members of the hospital staff.

American Academy of Railway Surgeons.—This Society held its annual meeting at the Auditorium Hotel, September 12th and 13th, under the presidency of Dr. D. S. Fairchild of Clinton, Iowa. The following officers were elected for the ensuing year: President, Dr. A. F. Jonas of Omaha, Neb.; First Vice-

President, Dr. L. Sexton of New Orleans, La.; Second Vice-President, Dr. Wm. H. German of Morgan Park, Ill.; Secretary and Treasurer, Dr. T. B. Lacey of Council Bluffs, Iowa; Editor, Dr. R. Harvey Reed of Rock Springs, Wyoming; Committee on Program, Dr. A. F. Jonas of Omaha, Neb., Chairman. Place of meeting, Kansas City; time, to be decided by Program Committee.

Incorporation of Christian Hospital.—The Christian Hospital has been incorporated by Dr. Emma M. Moore and others, with a capital stock of $25,000.

GENERAL.

A Royal Nurse.—The Princess Frederick Augusta, daughter of the Grand Duke of Tuscany and heiress to the throne of Saxony, is now taking a regular course of training in the Lutheran Hospital at Dresden. At her own request no distinction is made between her duties and those of the humblest probationer.

King Edward's Health.—Since his accession King Edward has enjoyed rather better health than formerly, but some anxiety is felt concerning his throat despite the assurance that the local trouble is of a very simple nature.

Epidemic of Baldness in Japan.—There was an epidemic of baldness at Chiba last year, and there has been an even more serious one quite recently at Osaka, the same province, where, as it will be remembered, an extensive epidemic of plague prevailed during the winter of 1899 and 1900. The clinical course of the affection under consideration offers many points of interest, and differs eminently both as regards extent and character from the occurrence of sudden baldness after enteric or any other acute fever. For it is stated that during that epidemic of baldness the loss of hair comes after very little, if any, premonitory warning. The bald patches are irregularly spread over the head, but the first large one generally appears on the crown and extends down the back of the head instead of forward toward the forehead; the opposite of the course of baldness as it is known in America. Another point which may be noticed is that most of the victims of the epidemic are women, and more children are attacked than men.

A Fatal Epidemic in Alaska.—The Rev. Father Rene, of the Alaska Catholic Mission, brings an account of a fearful malady which he describes as an apparent combination of cholera and grip that has caused more than three thousands deaths among the Yukon Indians during the past fall and winter.

Artificial Food for Microbes.—One of the chief difficulties in the chemical study of microbes has been the lack of a standard nutritive medium on which to grow them. A number of special media have been devised for particular bacteria, but no universal food substance suitable for the chemical laboratory has yet been obtained. The difficulty has been to provide the nitrogen which they require in a suitable form. At a recent meeting of the French Academy a note was read from M. Charles Lepierre describing a compound which he believes fulfils many of the requirements of such food. This is mixed with glycerin and small quantities of common salt, magnesium sulphate, calcium glycero-phosphate and bicarbonate of potash. With this mixture M. Lepierre has raised forty-five different microbes, twenty-two of which were pathogenic. Among the latter were the typhoid and cholera bacillus.

Doctor's Winged Messengers.—Dr. Gould, of Rockland, Maine, has a loft of homing pigeons. In practising his profession upon the islands adjacent to his coast, it sometimes becomes necessary to make tiresome and even hazardous trips in small boats. To avoid the unnecessary repetition of these he has fallen upon the plan of leaving pigeons at the homes of his distant patients, and by this means can be daily advised of their progress.

Epidemics in Schools.—At Hempstead, Long Island, scarlet fever has made it necessary to close the public school. The disease is very prevalent and attacks persons of all ages. No definite source of the contagion has been discovered, although the milk supply is suspected.—The Lincoln school, situated at Dunellen, N. J., has been closed on account of an epidemic of typhoid fever.

Smallpox in the United States.—Between June 28th and September 15th of the present year there occurred 9,503 cases of smallpox in this country with 265 deaths. During the corresponding period of 1900 there were reported 3,818 cases with 114 deaths. The distribution of the disease appears to be alarmingly general. A very unusual prevalence of smallpox is also reported from London, where it is credited to the neglect of vaccination.

Pecuniary Damages for Smallpox.—Two physicians of Red Bank, N. J., have been sued for ten thousand dollars by a man and his wife, the latter of whom contracted smallpox while acting as nurse to patients of these gentlemen. In the suit the plaintiffs aver that they were assured by the medical attendants that there was no danger of contagion.

A Function for the Appendix.—Dr. Hershey, of Denver, Colo., has advanced the theory that the appendix has a secretory function, serving as a lubricant to the large intestine, and that any interference with the organ brings about other forms of sickness and a multitude of disorders, including fatal constipation. Dr. Hershey will conduct experiments and report on his observations a year hence.

Progress of the Bubonic Plague.—Except on the island of Formosa the plague appears to be under control throughout China and

Japan. In the Philippines, however, a moderate number of cases are weekly reported among the Chinese and natives, although American soldiers are occasionally included among the victims. Deaths are reported in Siam, Mauritius and Cape Colony, while from British India, particularly in the neighborhood of Bombay, an appalling death-rate continues. Constantinople is still infected.

Novelties in Baths.—The mud baths so much in vogue at St. Amand-les-Eaux and elsewhere on the Continent are too well known to be considered new or unusual, but the invigorating effects of the wine bath are not so generally appreciated even by the wealthy. Bathing in milk, veal-broth or the yolks of eggs for the supposed influence upon nutrition is practised from time to time by the eccentric. The snow bath recommended by an athletic member of the Northwestern University at Chicago cannot be accused of having the element luxurious effeminacy which might be thought to characterize those already mentioned. This balneal diversion is only enjoyed in winter and is carried out by its advocates preferably just before retiring. After divesting oneself of all clothing, a longer or shorter time, "according to taste," is spent rolling about in the nearest snowdrift.

The Doctor in Fiction.—It would seem that it is impossible for the novelist to touch upon things medical without falling into error. Mr. Hall Caine, who gave us an impossible nurse in "The Christian," gives us a still more impossible medical man in his last novel, "The Eternal City," which has just been published. In the chapter entitled "The Roman of Rome," he describes how a practitioner examined the breast and axilla of a patient and, finding cancer, declared that a nurse must be summoned immediately. Further on, in speaking of the case, he is made to say that if the diagnosis had been made earlier *nephrectomy* might have saved the patient, but, as it was, the case was beyond surgical aid.

Operation was Necessary.—A distinguished specialist in abdominal troubles in London, speaking about President McKinley's case, said the best surgeons in Europe were unanimous in asserting that the operation was the right and the best thing that could have been done, and that the President would have died in forty-eight hours had it not been performed.

Foreign Comments.—The *British Medical Journal*, discussing the results of the autopsy says it is needless to assign any influence to the escape of pancreatic secretions or to a poisoned bullet, because the mechanical conditions "amply account for all disturbances found." The journal testifies to the high rank of American surgery and says: "Success in such a case would have been a triumph, and defeat is not disgrace."

Nerve Nostrums.—Dr. Wm. P. Spratling, of Craig Colony for Epileptics, Sonyea, N. Y., is preparing, by request of Dr. George F. Butler, Chairman of the Section on Materia Medica, Pharmacy and Therapeutics, of the American Medical Association, a paper on "Nerve Nostrums and Their Dangers" for the June, 1902, meeting of the American Medical Association, and he would be glad to have physicians and others send him any samples or literature of such nostrums coming under their notice, or tell him of them and where they may be procured.

No Dissension.—That certain of the daily papers should have persistently exhibited a disposition to disturb the harmony among the surgeons and physicians connected with Mr. McKinley's case, cannot be regarded otherwise than unfortunate by any who hold in proper respect the dignity and good name of the profession. It is particularly regrettable that any medical man should have lent his name to such efforts. Under the circumstances we are not surprised that the following statement has appeared:

"We desire to say to the press and the public, once for all, that every such publication and alleged interview with any of us containing criticism of one another or of any of our associates, is false and is nothing but scandal mongering. We say again that there was never a serious disagreement among the professional attendants as to any of the symptoms or as to treatment of the case or as to the bulletins which were issued. A very unusual harmony of opinion and of action prevailed all through the case.

"The unfortunate result could not have been foreseen before the unfavorable symptoms declared themselves late on the sixth day, and could not have been prevented by any human agency.

"Pending the completion and publication of the official reports of the postmortem examiners and of the attending staff, we shall refuse to make any further statements for publication, and alleged interviews with any of us may be known to be fictitious.

"MATTHEW D. MANN, ROSWELL PARK,
"HERMAN MYNTER, EUGENE WASDIN,
"CHARLES G. STOCKTON."

Obituary.—Dr. William McKinley, a well-known practising physician and a distant relative of the late President McKinley, was found dead at his home, at Polk, Pa. On Saturday Dr. McKinley was in Franklin, and with much emotion discussed the shooting and death of the late President with friends. He was of a highly nervous disposition and at different times during these discussions he became greatly excited over the assassination. In the evening he returned to Polk and a few hours after his arrival there his dead body was found by a member of the family lying on the ground in the rear of his residence. The phy-

sicians who were summoned said that death was due to apoplexy, brought on by the excitement of the day. Dr. McKinley had an acquaintance with President McKinley, and was one of his warmest admirers. He was a graduate of the Baltimore Medical College and forty-four years of age.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, Sept. 7, 1901.

A ROYAL COMMISSION ON TUBERCULOSIS—THE COMMISSIONERS—PROFESSOR KOCH AND THE BRITISH COAST.

A third Royal Commission has been appointed for the investigation of the tuberculosis question. This is the direct outcome of Koch's sensational deliverance at the recent Congress. The Commission is to inquire and report whether tuberculosis in animals and in man are one and the same disease; whether animals and man can be reciprocally infected with it; under what conditions, if at all, the transmission of the disease takes place, and what are the circumstances favorable or unfavorable to such transmission. There are five Commissioners, all members of the medical profession, though one of them is a representative of veterinary science. The University of Cambridge is represented by Sir Michael Foster and Professor Woodhead; no other university in the Three Kingdoms is represented. Professor Sidney Martin of University College of London, naturally finds a place on the Commission, as it was largely on his experimental work that the report of the last Royal Commission as to the dangers of the consumption of tuberculous meat and milk was based.

Dr. John McFadyean is our greatest authority in this country on veterinary pathology, and Professor Boyle, of Liverpool, is in the sphere of pathology as "pushful" as Mr. Chamberlain is in politics. Sir Michael Foster is a physiologist, and, as far as I know, has given no special attention either to tuberculosis in particular or to pathology in general. But he is a fine ornamental figurehead, and being at once head and indeed part creator of the medical school of Cambridge, Secretary (which virtually means "boss") of the Royal Society, and a Member of Parliament; he is a personage of great importance. He speaks well, and is really an able man, though he looks at the world a little too much through academic spectacles. Professor Woodhead is an industrious worker, whose name is not associated with any great original discovery; but he is a teacher of very marked capacity and has studied tuberculosis from all points of view for many years. On the whole, it is in a scientific sense a strong Commission, but unfortunately the problems of pathology cannot be solved even by Commissions issued "under the King's Royal Sign Manual." There are among the constituent element on the Commission certain factors which may impair the value of its findings. Thus, one of the Commissioners has already shown that he does not approach the question in that spirit of absolute impartiality which the investigation of a scientific question demands by declaring that the organizers of the Tuberculosis Congress should never have allowed Koch to read his paper!

I see it is stated by a writer in one of your contemporaries that Koch, after shooting his bolt, "evaded the result" by leaving the arena. That is Koch's way. His words are to be accepted with the faith demanded of the subjects of an infallible oracle. But when your contemporary goes on to attribute to disinclination to defend his position, Koch's avoidance of social entertainments and in particular his absence from the group of delegates presented to the King he goes somewhat astray. Koch is, owing to circumstances that need not be referred to, rather an outsider from the social point of view, and it is understood that the German Court did not recommend him for any special attention on the part of Royalty here.

TRANSACTIONS OF FOREIGN SOCIETIES.

THE MENINGOCOCCUS OF WEICHSELBAUM—INTOXICATION BY DYES IN SHOES—METAMERIC ZONE OF THE LOWER EXTREMITY—LEUCOCYTOSIS OF MEASLES—LESIONS IN THE TERMINAL SPINAL CORD FILAMENTS—HYSTERICAL PSEUDOMENINGITIS—THE KIDNEYS AND TUBERCULOSIS—SENSIBILISATRICE IN TYPHOID SERUM—THE BACILLUS TUBERCULOSIS AND THE FECES.

M. Landouzy, at the Académie de Médecine, July 30, 1901, read a report on the experimental transmission of the meningococcus of Weichselbaum by the respiratory channels. The meningococcus was found in the mucous nasal discharges of five soldiers who were suffering from epidemic cerebrospinal meningitis. Inoculations with this mucus were made in the nasal cavities of five guinea-pigs and three rabbits. All eight of these animals became sick and five died. In the cerebrospinal fluid of these free meningococci were demonstrated. Again inoculations from the nasal mucus of this set of animals upon an other set resulted in death and the recovery of this meningococcus in pure culture from their cephalorachidian fluid. Likewise the depositing of some of the cerebrospinal fluid from one of the deceased soldiers upon the nasal mucous membrane of a rabbit and three guinea-pigs resulted in causing the same series of symptoms as in the other lots of animals and in the death of two of the guinea-pigs. In the spinal fluid of these the meningococci were again freely present.

M. Landouzy also read a communication in the name of M. Lop (Marseilles) relative to a peculiar example of poisoning by dye-stuffs as

employed to color leather. His patient was a young boy who having bought a pair of yellow boots determined to dye them black. The evening of the first day of wearing them he was seized with grave symptoms, cramps in the calves, nausea, vomiting, hypothermia, cyanosis of the face and extremities, anuria, etc. Upon careful investigation it was evident that these symptoms were all due to intoxication by the dye, aniline in character, he had used in coloring his shoes. This observation is analogous to that presented to the Academy by Landouzy himself about one year ago. Together they serve to emphasize the dangers inherent in employing dyes on the shoes and might suggest the propriety of bringing the matter to the notice of the proper authorities.

M. WIDAL, at the Société Médicale des Hôpitaux, July 26, 1901, noted an observation of the metameric zone of the lower extremity in collaboration with M. Le Sourd. The woman was forty-nine years old and the right thigh was affected. The vesicles were arranged for the most part in transverse bands, extended in front from the groins almost to the knee and from the popliteal space almost to the lumbar region behind. Examination of the cephalorachidian fluid demonstrated numerous lymphocytes, just as in the cases reported at a previous meeting by M. Brissaud and M. Sicard. The facts argue strongly for the existence of some medullary changes which involve also the pia mater. Because it is well established to-day that a purly ganglionic change could not produce these changes in the cephalorachidian fluid. Bacteriologically this fluid was sterile, as all inseminations upon culture-media gave no growth.

M. J. GOURMONT (Lyons) addressed a note in the names of Montagard, Pehu and himself relative to the special type of leucocytosis present in measles, with definite reference to distinguishing the rash of measles from that of variola. According to these writers measles is accompanied by a slight hyperleucocytosis, which is augmented as soon as any complications occur, purely of the polynuclear cells. They have not yet observed myelocytes, nucleated red cells nor mononuclear leucocytes. On the other hand the eosinophile cells are decreased in comparison with the normal number for children, which distinguishes the disease from scarlatina, if the observation be true, because scarlatina is manifested by an increase in the eosinophile cells.

M. HIRTZ gave the history of a young man, thirty years old, who died of pulmonary tuberculosis, with decided uremic symptoms, consequent upon an albuminuria. The autopsy showed a large cavity at the apex of the right lung, and the kidneys white, lardaceous and upon microscopical view in a very marked degree of amyloid degeneration.

M. WIDAL and M. Le Sourd, at the Société de Biologie, July 29, 1901, presented a collaboration dealing with the presence of *sensibilisatrice* in typhoid serum. The special point they sought to demonstrate is the day at which it appears in the blood of guinea-pigs, inoculated beneath the skin with a culture of the bacillus typhosus. The method of fixation was that employed by M. Bordet. In two animals the *sensibilisatrice* appeared on the fifth day accompanying the phenomenon of agglutination. In a third animal it preceded the latter by one day. Among the human patients at their disposal they always found the two phenomena, agglutination and fixation co-existing. In not one case were they dissociated and always were present in the earlier days of the disease. In one patient they appeared as late as the sixth day. Otherwise both existed before that time. A dissociation of these two signs can, however, be clinically found. For example in one patient who had fully recovered from a mild degree of typhoid fever, the agglutination property in his blood had disappeared four months after his convalescence, but the fixation property was still present. In another patient who had already had three relapses of the disease both of these signs were beautifully marked, and that of fixation was the most distinct they had yet seen. A dilution of 1-300 still gave agglutination, Yet four days later a fourth relapse took place with all the typical signs and symptoms. Such a fact appears to demonstrate that immunity does not co-exist with the sign of fixation.

M. ANGLADE (Aleneon) stated that he has been investigating the alvine dejections of tuberculous patients and has found them a large avenue for the elimination of the bacillus, alike in those who have pulmonary as in those who have intestinal tuberculosis.

SOCIETY PROCEEDINGS.

HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

Stated Meeting, Held May 25, 1901.

The President, Howard Lilienthal, M.D., in the Chair.

Advance in Knowledge of Gonorrhea.—Dr. Frederick R. Sturgis read a paper on recent advances in knowledge of the pathology of gonorrhea, with special reference to the question whether the disease should not really be considered a constitutional affection with a local manifestation. He said that formerly it was thought that gonorrhea was an absolutely local disease. It was the custom, too, to consider it as a rather mild form of inflammation that ran a definite course and left no serious sequelæ after it. The question of the significance of complications of the disease was not so clear. Serious complications were known not to be rare, though they were considered to be only passing in their effect.

Systemic Infection.—Of late a good deal of material has been accumulated with regard to the systemic involvement in many cases of gonorrhea. Generalized infection means absorption of

septic material from some localized focus containing pyogenic micro-organisms. There is now no doubt in the minds of most physicians that absorption of this kind takes place during the course of gonorrhea and that it produces constitutional symptoms in a goodly proportion of cases.

Manner of Auto-infection.—It has been known for some time that the gonococcus readily attacks circumjacent tissues. It spreads by continuity of tissue as well as by contiguity. It was not thought, however, that it produced generalized infection. It was known that it affected the joints and the eyes, but these processes were called metastatic. Over a hundred years ago John Hunter thought that, as gonorrhea attacked joints, so it also affected the endocardium. His idea met with no general acceptance, however, and Trousseau combated the idea of gonorrhea wandering in this way. About the middle of the century a number of cases were reported that pointed clearly to the fact that gonorrhea might produce a sort of pyemia. It was not, however, until Neisser's discovery of the gonococcus and Bumm's description of the method of cultivating it that any trustworthy investigation could be carried out.

Organs Affected by Gonococcus.—It is now known positively that most of the organs of the body can be affected by the gonococcus. It has been found in the kidney, producing pyelonephritis in the pus of which a pure culture of the gonococcus has been demonstrated. It has been found in the coverings of the brain, producing severe serous meningitis and also purulent affections of the meninges. It has been found in the intramuscular tissues with tendencies to produce abscess. It is well known that rectal infections by the gonococcus may of themselves, or by the secondary infection which they favor, lead to very serious ulcerative conditions of the rectum. Finally, the gonococcus has been found in the spleen, in the periosteum of the bone and even free in the circulation. In a word, no tissue or organ is exempt from invasion by the micro-organism that only a few years ago was considered to limit its ravages to the specialized mucous membrane of the genito-urinary tract and the conjunctiva.

Mixed Infection.—It has often been claimed that the secondary symptoms and complications and many of the sequelæ of gonorrhea are really not due to the gonococcus itself, but to various pyogenic organisms which find a favorable occasion for entrance into the tissue, because of the presence of the chronic inflammatory lesions produced by the gonococcus. The staphylococcus was thought to be the most frequent secondary infective agent and its presence has been shown in a number of these cases. There is no doubt, however, that, while the gonococcus predisposes to secondary infection, it can of itself in pure culture produce serious pyogenic conditions. Prof. Finger of Vienna in 1895 showed that malignant endocarditis may be caused by pure cultures of the gonococcus alone. He demonstrated the presence of the gonococcus on the valves of the heart in pure culture by staining and culture methods.

Subsequent Confirmation.—Within a year or two after the announcement of his discovery, Finger's conclusions in this matter were substantiated by investigations at Johns Hopkins Hospital. Thayer and Lazear demonstrated the presence of gonococci in pure culture in a tricuspid lesion of the heart. A little later Brantford Lewis showed that the only organism to be found in a case of pyelonephritis under his care was a biscuit-shaped diplococcus which had all the characteristics of the gonococcus. It grew well only on urine agar and it conformed to the Gram test. This case had been considered one of malaria, because of the regularity with which the chills recurred from day to day. The patient strenuously denied ever having had gonorrhea.

Secondary Infection.—Dr. Arpad Gerster in a case of septicemia originating in a kidney abscess found staphylococci and gonococci in the kidney pus. It seems easy to explain the presence of gonococci in the kidney by claiming that it spreads by continuity of tissue, the micro-organism finding its way through the bladder and ureter to the pelvis of the kidney. In most of these cases, however, there have been absolutely no symptoms of bladder or ureteral disturbance and it seems more reasonable to suppose that the kidney infection has taken place either through the lymph-channels or perhaps directly through the blood during an effort of the kidney to eliminate the micro-organism from the circulation.

Brain and Spinal Symptoms.—In most of the cases where there have been brain and spinal symptoms, it has not been clear that there was direct infection of any of the structures in or around the nervous system by the gonococcus. Symptoms seem to have been produced either by mixed infection or by the toxins in the circulation absorbed through some focus of gonococci at a distance from the nervous system. In Fuerbringer's case there were distinct epileptic attacks that seemed to be traceable to gonorrheal influences.

Nervous Lesions.—Fuerbringer's case is interesting because it exemplifies exceptionally serious conditions. The patient when admitted complained of pains in his head and abdomen and was restless and sleepless. He was strong and well built, his pupils were dilated and his optic papillæ were found somewhat congested. A short time after admission he complained of a stiff neck and became very restless, wanting to be continually in movement. He had on admission an acute urethritis with a profuse discharge of yellowish purulent material. Lumbar puncture was performed and about 20 cubic centimeters of purulent fluid were evacuated from the spinal canal. In the cells of this purulent fluid diplococci were found resembling gonococci in all bacteriological peculiarities. The patient became comatose and death took place the next day.

Postmortem Findings.—At the autopsy the spinal cord was found surrounded by purulent fluid and the pia mater of the brain was congested with pus. There was marked edema of the nervous tissue and to this evidently most of the nervous symptoms could be referred. Bacteriological examination of the pus obtained after death gave the same results as in that obtained by lumbar puncture. The diplococci found were thought to be gonococci. Some doubt, however, was expressed as to whether the micro-organism might not possibly be the meningococcus intracellularis of Weichselbaum. This micro-organism is generally accepted as the cause of epidemic cerebrospinal meningitis. Sporadic cases of this disease may be seen almost at any time, especially in European cities.

Cutaneous Infection.—The skin seems to be very little liable to infection by the gonococcus, yet some cutaneous and subcutaneous lesions have been noticed. Petechiæ, for instance, have been described as occurring in some cases and purpura of the lower limbs has been reported. Hematuria and even epistaxis have at times been attributed to the presence of gonococci, though usually there has been mixed infection of staphylococcus albus. In one case an indurated, red, pointed blotch occurred in the skin during the course of a series of relapses of gonorrheal arthritis.

Septic Conditions.—There is little doubt in most minds now that septic conditions can be produced by the presence of gonococci alone. In some unknown way the presence of gonococci in any part of the body seems to favor the occurrence of mixed infection. This it is that makes the definite etiology of lesions that occur during the course of gonorrhea so difficult to settle. As a rule, one should not speak of gonorrhea, but of gonococcal infection.

Gonococcal Toxins.—There is supposed to be a toxin produced by the growth of the gonococci the absorption of which causes certain of the constitutional symptoms familiar in gonorrhea. This toxin has, however, never been demonstrated and its existence is entirely hypothetical.

Avenues of Systemic Infection.—There are two ways by which the gonococci can find an entrance into the system, namely, through the blood-stream and through the lymphatic current. Spread of the gonococci through the lymphatics is well established. The occurrence of buboes in the inguinal glands is usually due to mixed infection, but in a certain number of cases a pure culture of diplococci with all the bacteriological characteristics of gonococci have been found. Often when other pus micro-organisms can be demonstrated gonococci are also present.

Generalized Infection.—Since the occurrence of gonorrheal arthritis and gonorrheal endocarditis makes it clear that gonococci can be transported by the blood-stream, the only rational conclusion is that constitutional infection by the gonococci is not so rare as it has been thought. It has been demonstrated that gonococci may occur in pure culture within the heart or in the arterial blood. It may not be said, perhaps, that it is a constitutional disease with a local manifestation, but it must be admitted that, while mainly a local disease, it is capable of producing systemic disturbances and may become generalized.

Latent Infections.—Dr. Robert H. Greene said that a much larger proportion of cases of gonorrhea than has been hitherto imagined have prostatic infections. These escape detection for the most part. Gouley found granulomatous processes in the prostate, the result evidently of chronic inflammation extending over a long time, in cases where there had been practically no symptoms of such a condition. Undoubtedly there are cases in which constitutional symptoms are noticed very early in the course of the disease. At times, too, these constitutional symptoms are noted without any serious preliminary symptoms of the disease. The primary acute stage is entirely latent and there is an insidious involvement of other parts because of infection through the lymphatics.

Influence of Soil.—Dr. Eugene Fuller said that undoubtedly gonorrhea starts as a local infection and should be considered as such. The tissues of certain individuals, however, make an especially favorable soil for the growth of the gonococcus and so the whole system may become infected. In some individuals there is very little resisting power to gonococci invasion. Many of the complications, especially those at a distance from the original focus of disease in the urethra, seem to him to be due to mixed infection. The cause of the complication is really some other micro-organism that finds a favorable opportunity for entrance through the lesions produced by the gonococcus. It has always seemed to Dr. Fuller that the gonococcus is only an incident in the serious complications and sequelæ that sometimes occur.

Lowering of Resistive Vitality.—It seems not improbable that the presence of the gonococcus and of its toxins in the system may lower resistive vitality very much. It is now well known that people stung by snakes, when they escape the acute effects of the snake poison, may die of general septicemia sometime afterward as the result of the invasion of pus micro-organisms, the snake poison having robbed them of all resisting power. Most men in the special practice of genito-urinary diseases have seen some of the cases in which the patient seemed to be robbed completely of resisting power. They are very severe cases and usually are well impressed upon the physician.

Fulminant Case.—Dr. Fuller gave the details of a typical example of these fulminant cases. The patient was a large, strong, healthy man who had an attack of gonorrhea in an early stage. In the course of attendance on business he was obliged to go West. He did this all the more readily as he did not care to explain his condition to his wife. While on the train at Pittsburg he had a severe chill and high fever de-

veloped. He became delirious and his temperature was found to be above 104° F. He was removed to a hospital. His endocardium became affected, both kidneys became involved and severe arthritis of the shoulder-joint developed. He came out of this acute attack a wreck. He has improved greatly, but there is still albumin in his urine and his shoulder is somewhat stiff.

Significance of Such Cases.—Undoubtedly such attacks shorten life. They remind one of nothing so much as the fulminant puerperal septic conditions that sometimes develop without explicable cause after delivery. They run an almost exactly similar course, they submit the patient to the same serious risks and they are apt to leave the same annoying sequelæ. The cause for the infection seems to be the predisposition produced by the lowering of resistive vitality.

Gonorrhea Local in Women.—Dr. Egbert H. Grandin said that in gynecological practice one does not see the constitutional symptoms of gonorrhea as frequently as they seem to occur in the practice of specialists in diseases of the male. The gonococcus in woman seems to spread always by continuity, most frequently from the vagina to the cervix and then to the uterus and tubes and, finally, to the ovaries, with an occasional involvement of the peritoneum; or it spreads from the urethra to the bladder and thence to the ureters and kidneys. One sees chronic gonorrhea often enough and would expect to see systemic infections, if the gonococcus were prone to produce constitutional involvement. In woman at least this does not seem to be the case very often.

More Suitable Terms.—Dr. Reynold W. Wilcox said that the question presented for discussion by Dr. Sturgis was very timely. He hoped that it would enable us to get rid of the term "gonorrheal rheumatism," since arthritis complicating gonorrhea is in no sense of the word rheumatic. It used to be said that the differential diagnosis between gonorrheal rheumatism and acute rheumatic arthritis could be made from the fact that in gonorrheal arthritis no heart complications occur. It was also said that gonorrheal rheumatism was usually mono-articular. One of the worst cases of generalized arthritis that Dr. Wilcox has ever seen was gonorrheal in origin. Nearly every joint of the spinal column was affected and, as some ankylosis ensued, the patient became distinctly kyphotic.

Second Attacks of Syphilis.—Dr. Wilcox requested permission to ask a question with regard to second attacks of syphilis. A young lawyer some eight or nine years ago was treated for syphilis. He had a typical chancre and secondary symptoms and antisyphilitic treatment was continued for about two years. He remained for over six years without a lesion of the disease. About six weeks ago he contracted a discharge that seemed to be gonorrheal in character. After a time this improved and about three weeks after exposure he developed a typical chancre. Since then he has had a general roseola together with headache, feeling of general malaise and some temperature. His symptoms all point to a second attack of syphilis. While, of course, such cases have been reported a number of times, Dr. Wilcox wished to know if they were at all frequent in ordinary genito-urinary practice.

Status of the Gonococcus.—Dr. Follen Cabot said that the bacteriological status of the gonococcus is yet not entirely settled. Very few doctors are willing to take the responsibility of deciding with assurance on the absence of gonococci when there has once been an attack of gonorrhea and the patient thinks of marriage. Even after two or three examinations the bacteriologist is apt to be non-committal in his declarations.

Cultural Differences.—Dr. Cabot said that Dr. Dora Williams has found many cultural differences even between apparently genuine forms of the gonococcus. Certain gonococci grow readily on two-per-cent. agar. Others grow poorly at first, but learn to grow well on this culture medium after having passed a number of generations on it. Certain others fail to grow at all. After transference from one batch of medium to another the gonococci are apt to grow spasmodically, sometimes they grow well, sometimes poorly, sometimes not at all. Even the most vitally active forms can not be depended on to grow with regularity. Whether such cultural characteristics in the micro-organism are sufficient to constitute types of gonococci, or are only unimportant peculiarities dependent on unessential qualities further study along this line will show definitely.

Old Time Infectious Discharges.—Dr. Cabot has recently had under his care a man who had been married for fifteen years, who absolutely denied any possibility of infection outside of the conjugal relations. About four or five days after conjugal relations a discharge began, not severe at first, but which lasted for several weeks and then yielded only to antigonorrheal treatment. In the discharge there were found diplococci resembling gonococci, but it was practically impossible to say that they were surely gonococci. We are not in a position as yet to settle such a question with absolute assurance by bacteriological methods.

Diplococci in Spinal Fluid.—Dr. R. J. Wilson said that in a recent case he found a diplococcus in the spinal fluid. This diplococcus was not unlike the meningococcus intracellularis of Weichselbaum. There was in the case a malignant endocarditis and cultures taken from the blood showed the presence of a corresponding micro-organism in the circulation. Severe arthritis developed and from the arthritic fluid micro-organisms were obtained which grew on ordinary agar and ordinary bouillon. Only a few delicate colonies were obtained and these were transferred to blood serum. They were found to be composed of diplococci which stained as gonococci, but grew on ordinary agar. As a consequence it was thought at first to be a meningococcus, but later on was thought to be a gonococcus. The

cultures on agar died out and no further history could be obtained.

Diplococci and Malignant Endocarditis.—In a patient under observation two years ago, malignant endocarditis developed and lasted for five weeks. Fifteen cubic centimeters of blood were taken for culture purposes, but without result. At a second culture attempt diplococci were obtained which grew on glucose peptone. The urine was then examined and cultures taken from this fluid. Other bacteria were present, but diplococci not unlike gonococci were also obtained. Pleuritis came as a complication in this case and sixty to seventy ounces of fluid were removed. Chronic diffuse nephritis was also found to exist. The physical signs of an aneurism developed over night. A number of petechæ occurred around the point whence the blood had been taken. Purpuric spots occurred on the trunk and arms.

General Infection from Gonococci.—When Thayer made his discovery of gonococci upon the heart valves it was thought that a number of these cases would be found. This expectation has not been fulfilled. Undoubtedly the gonococci do produce a systemic infection, but it is extremely hard to find them in pure culture. One cannot make any definite conclusions, as yet, as to whether the systemic infection is as a rule due to the gonococcus alone, or to mixed infection.

Analogy with Surgical Sepsis.—Dr. Howard Lilienthal said that undoubtedly gonorrhea may become constitutional, just as acute surgical infections find their way into the system. This is not apt to occur so rapidly from gonorrhea as in the infections by more distinctly pyogenic organisms. There are distinctions, of course, in the virulence even of the frankly pyogenic microbes. Staphylococci usually produce local thrombosis of a vein and then, from the clot thus formed, find their way into the blood. This produces the metastatic condition, the basis of septicemia. Streptococci act similarly, but more virulently.

Meddling with Urethra.—Dr. Lilienthal is of the opinion that uncalled-for meddling with the urethra often proves a fertile source of the generalization of gonococcal infection. The cutting and stretching of strictures, except where it is absolutely necessary, should only be done with the greatest care. Injury may mean the production of metastases. There should be very little direct treatment of an acute gonorrhea in order to avoid even the slightest trauma of the urethra at a time when the gonococci are virulent, or when secondary infective material is present with the gonococci.

Pyemic Poisoning.—Dr. Sturgis in closing the discussion said that undoubtedly quite often during the course of a gonorrhea a pyemic poison develops which is due at times to the presence of a mixed infection and at times to a pure culture of the gonococci. There remains the question, Is there a pseudogonococcus—a double of the microbe producing ordinary gonorrhea and which has under certain conditions a special virulence? Has this organism practically the same morphology as the gonococcus, and does it resemble it so closely as to be mistaken for it, as in Fuerbringer's case? There seems at times to be toxic symptoms in patients suffering from gonorrhea that can only be attributed to the presence of ptomains in the circulation due to absorption of the products of gonococcal growth at the point of local inoculation. This theory of a special toxin would account better than any other for certain symptoms the source of which is not at present understood.

Second Attacks of Syphilis.—Dr. Sturgis is of the opinion that second attacks of syphilis are not so rare as they are sometimes thought. It is probable that reinfection took place in Dr. Wilcox's case. Dr. Sturgis has had two cases in which he felt sure that a second attack took place. In the history of these cases it is usually a noteworthy fact that the first attack is very light. Mild syphilis seems not to communicate much immunity.

Dr. Eugene Fuller said that he had seen at least two cases in which he felt sure that second attacks of syphilis had taken place. It is, however, a rare condition. Some years ago he saw an English traveler who claimed to have had a primary sore while in India and less than a year afterward another primary sore while in China. It is probable that this second sore was really nothing more than a mucous patch on the foreskin.

Epithelioma of Penis.—Dr. Hawkes presented a specimen of an epithelioma of the penis for which the whole organ had been removed. The first sign of the affection was a small nodule under the foreskin. This was hard and presented some diffuse induration. It made the foreskin non-retractile. Circumcision was recommended and performed. A similar nodule appeared afterward on the scar of the circumcision wound and later at the meatus. The inguinal glands became involved; these were removed, but their involvement proved to be only inflammatory in character. There is every reason to hope that the cure will be radical.

Dr. Grandin suggested that more careful investigation should be made as to the origin of such epitheliomata, especially as regards the possibility of infection from an epithelioma of the cervix in the patient's wife. He has seen some cases that led him to suspect this etiology of penile epitheliomata.

Very Large Prostate.—Dr. Fuller presented a very large prostate which he had removed by the suprapubic method, splitting the mucous membrane of the bladder at the trigone and shelling it out. Though this tumor was so large and the operation was done only six days ago, the patient is convalescing without incident.

Dr. Howard Lilienthal said that in removing large prostates he has found Dr. Fuller's suprapubic method very satisfactory. There is very little risk, the operation is clean and done under the eye, and the convalescence is reasonably rapid, while the results are eminently satisfactory.

BOOK REVIEWS.

Progressive Medicine. A Quarterly Digest of Advanced Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Vol., II. June, 1901. Lea Brothers & Co., Philadelphia and New York.

Progressive Medicine continues to maintain the same useful characteristics which have made it an indispensable feature in the physician's library. It might be termed a series of critical digests of contemporaneous medical research. The present volume comes from four authors. Dr. W. B. Coley presents the advances made in the surgery of the abdomen, including hernia; Dr. John G. Clark, those new procedures and advances in the sphere of gynecology; the diseases of the blood and ductless glands; the hemorrhagic diseases and diseases of metabolism are splendidly handled by Dr. A. Stengel, and the subject of ophthalmology is covered in a complete and thorough manner by Dr. Edward Jackson. In Dr. Coley's article, in addition to the critical and collected résumé of the literature on abdominal surgery, particular attention has been given to the subject of the surgical treatment of malignant diseases of the intestines and rectum. The illustrative features of this section are excellent. Dr. Clark has given an excellent review of his own investigations on the ovary in the section devoted to gynecology.

We know of no publication in the English language that fulfils the objects so well as this. As a suggestion to the publishers, we believe that in the index, it would be an excellent feature to refer to previous volumes in which the last résumé of the subject was treated. In this manner the student can easily refer back, without loss of time. The absence of this system of back referencing, and the time lost by the reader in trying to find his subject are factors which, with increase in the number of volumes, deter many from starting a system of this type.

Atlas and Epitome of Labor and Operative Obstetrics. By Dr. Oskar Schaeffer, Privat Docent in Obstetrics and Gynecology in the University of Heidelberg. Authorized Translation from the Fifth Revised German Edition. Edited by J. Clifton Edgar, A.M., M.D., Professor of Obstetrics and Clinical Midwifery in the Cornell University Medical College. W. B. Saunders & Co., Philadelphia and London.

What has been said of the preceding volume can only be repeated in regard to this. Since there is no branch of medicine in which demonstration is so difficult as midwifery, a series of excellent plates such as abound in this book are next to actual bedside and amphitheater instruction, an absolute necessity to the student, especially since the criticism may be made that the usual text-books are too verbose and lacking in suitable illustrations. The plates in the first part of the work picture admirably the various presentations and positions during the different stages of labor, while in the second part the different operative procedures are clearly shown.

The Retrospect of Medicine. A Half-Yearly Journal Containing a Retrospective View of Every Discovery and Practical Improvement in the Medical Sciences. Edited by James Braithwaite, M.D. Consulting Obstetric Physician and Surgeon to the Leeds General Infirmary; Late Lecturer on Diseases of Women and Children, Leeds School of Medicine, etc., and E. F. Trevelyan, M.D., B.Sc., F. R. C. P., Assistant Physician to the Leeds General Infirmary; Professor of Pathology, Yorkshire College, Leeds. Vol. 123, January to June, 1901. Simpkin, Marshall, Hamilton, Kent and Co., Limited, London.

During the greater part of its sixty-two years of publication, Braithwaite's retrospect has been the source from which the British and American practitioners have drawn their information of what was being done in fields of medical science. But nowadays, the medical weeklies and monthlies provide the abstracts for which the "Retrospect" has been noted; so the editor, feeling that there is no longer need for his book, will publish no further volumes. The present issue contains, as usual, abstracts of a well-selected series of articles from British, American and continental journals. These are grouped under the headings of nervous system, digestive organs, etc. The book is of handy size so that it may be carried about, and is replete with articles of interest to the medical man. We cannot but feel regret that its publication is to cease.

A Practical Treatise on Diseases of the Skin for the Use of Students and Practitioners. By James Nevins Hyde, A.M., M.D., Professor of Skin, Genito-Urinary and Venereal Diseases, Rush Medical College, Chicago, etc., and Frank Hugh Montgomery, M.D., Associate Professor of Skin, Genito-Urinary and Venereal Diseases in Rush Medical College, Chicago, etc. Sixth and Revised Edition. Lea Brothers & Co., Philadelphia and New York.

The fact that one year has sufficed to exhaust a larger edition than was ever before published led to a thorough revision by the author and speaks well for the increasing favor in which their work is held. Following chapters on the Anatomy and Physiology of the Skin, General Symptomatology, Etiology, etc, the various diseases are discussed, the classification of Hebra being still adhered to as most practical for the student, though not sufficiently scientific for the expert. Among the diseases which have been rewritten are acne, herpes, psoriasis, scleroderma, tuberculosis, blastomycosis and carates, and the discussions on pathology have been brought up to the present day. The illustrations, printing and binding also deserve most favorable mention and we wish the book further well-deserved success.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXIX. NEW YORK, SATURDAY, SEPTEMBER 28, 1901. No. 13.

ORIGINAL ARTICLES.

A CONTRIBUTION TO THE SURGICAL RELIEF OF CANCER OF THE RECTUM: REVISION OF THE STATISTICS TO DATE, WITH SPECIAL REFERENCE TO SACRAL EXTIRPATION.*

BY FRANK LE MOYNE HUPP, A.M., M.D.,

OF WHEELING, W. VA.,

ATTENDING SURGEON TO THE CITY HOSPITAL.

SOME one has well said that the best doctors still try to "give Nature a chance." This should be true, yet the ablest surgeons of our time no longer hesitate to cut out from the internal economy of man all organs save the heart and brain. Gastrectomy was done by Schlatter, and the world marveled at his work. The chondroplastic method of pericardotomy with suture of the heart muscle is no longer fancy, but fact. Lilienthal extirpates the entire colon, the sigmoid and four inches of the ilium for hyperplastic colitis, and his patient lives to tell the tale.

Sarfert stays the ravages of the tubercle bacilli, with its resulting hectic fever and hemoptysis, by draining the multiple abscesses in the lung's apex.

Lange excised seven inches of the rectum after removing part of the sacrum and simultaneously through the yawning wound delivered an extensively adherent, multilocular ovarian cyst, the size of a child's head. Thus, in many ways the beginning of the twentieth century points out marked effort and improvement in the surgical means of alleviating suffering and saving life.

Cancer Defined.—In old St. Paul's churchyard, London, in the year 1751, Robert Brookes printed a book on the subject of physic, which contained the following definition: "A cancer is a hard, round, unequal, painful and generally immovable tumor, of a livid blackish, or leaden color, surrounded with swelled, crooked, varicous vessels, in some sort resembling the feet of a crab; and unless it be extirpated root, branch, and seed, it will be exasperated and strike inward, generate others and increase those already formed." A wonderfully true picture for the time it was written, and even true to-day.

But perhaps a more modern definition[6] comes from the pen of that distinguished author, Lewis S. Pilcher, who defines under the generic name cancer, "Those new growths, which, after they have once begun their formation, steadily continue the accretion of their own peculiar tissue, invade and replace adjacent tissue, progress at their periphery, while processes of necrosis cause the melting down of parts earlier developed, and, parasite-like, at the expense of tissues among which they develop, continue their progressive invasions and necroses, unchecked by any resisting power in the normal tissues, either already inherent in it or that can be brought to it by any mode of living or of medication."

Probably the most important pathological problem before modern medical science to-day is the mystery surrounding the etiology of cancer; yet it may be asserted with confidence that something definite and tangible has been reached through the untiring efforts and research of Dr. Harvey R. Gaylord.

Along with Major Walter Reed's startling demonstration at the recent Pan-American Medical Congress in Cuba, that the bite of the *Culex fasciatus* is sole cause for the propagation of yellow fever, this almost clinching proof of the protozoal cause of cancer marks the beginning of a new era in medicine, and these may justly be regarded as two of the greatest achievements of scientific research in modern times. For certainly the recognition, separation and cultivation of a disease germ, be it bacterial or protozoal, vegetable or animal, opens up the way for preventive medicine, and immediately suggests means for the relief of thousands of those everlastingly doomed to an agonizing death.

Pathology.—Dr. Warren, the distinguished surgeon to the Massachusetts General Hospital, speaks thus of the pathology:[27] "Carcinoma when found at the anus is of the pavement-cell variety, and when growing from the mucous membrane it appears as a cylinder-cell carcinoma. There are, therefore, in this locality both types of the so-called 'epithelioma.' The pavement-cell form, which takes its origin in the cutaneous coverings of the anus, begins as a warty or papillary growth that breaks down early and ulcerates. It is not unlike cancer of the lip in its early stages. The surrounding parts are more or less hard and infiltrated, and the edges of the ulcer are elevated and sharply defined. The growth spreads inward and involves the mucous membrane, and it invades also the external integument, involving the perineum or the commissure of the vagina and the labia in women. The cylinder-cell carcinoma, which develops from the follicles of Lieberkühn, begins as a more or less exuberant growth, which soon breaks down and develops into a crateriform ulcer involving more or less of the circumference of the bowel. This growth is found some little distance within the rectum, and it is often difficult for the exploring finger to reach its upper margin. The cells are arranged in acini, and they have a strikingly glandular appearance, closely resembling that seen in cancer of the

* Read at the meeting of the West Virginia State Medical Society, Grafton, May 17, 1901.

uterus. It is therefore often called 'adenocarcinoma' or malignant adenoma. This is the commonest variety of cancer of the rectum. Cancer occurs also in the medullary form, but more rarely. It is exceedingly malignant, and it soon infiltrates the walls of the rectum, converting the latter into a rigid tube and gluing it to surrounding parts. Scirrhous cancer is said to occur high up near the sigmoid flexure or in the neighborhood of the prostate. It infiltrates the submucous tissues, and the mucous membrane over it for a time appears healthy. It grows slowly and causes annular stricture, or it is felt as a hard nodule in the wall of the rectum."

Treatment.—Not many years ago a well-known text-book dismissed the subject of treatment in carcinoma of the rectum in words like these: "Treat symptoms and relieve pain as long as possible; as a last resource, do colotomy."

There still exists in the minds of the conservative doubt regarding the operative treatment of this disease. There are those who advocate the palliative colostomy, and are not willing to jeopardize the lives of their patients with any of the methods of excision, unless the neoplasm is engaging the first few inches of the rectum.

Treves[21] writes: "In no case should the peritoneum be deliberately opened, or a portion of the vagina, bladder or prostate excised. Experience has condemned these extensive operations."

Allingham[22] speaks thus conservatively: "To attempt to exercise the rectum when the growth is four inches up the bowel is most unscientific and unsurgical."

Harrison Cripps, surgeon to St. Bartholomew's, says: "If the finger can pass sufficiently beyond the disease to feel a healthy mucous membrane, so far as the height is concerned a satisfactory removal is possible."

Maylard,[23] surgeon to the Victoria Infirmary, gives his opinion as follows: "The question regarding this operation now comes to one of determining whether the good that it can effect sufficiently outweighs the untoward results that frequently follow; in other words, does the prolongation of life and the relief of suffering more than compensate for the lives it shortens and the often additional trouble it causes?"

Having referred to Czerny of Heidelberg, who reported a series of 36 cases operated on by sacral method with a mortality of 19.4 per cent., Maylard continues: "It need hardly be said that the question is one of extreme difficulty; for, even if it could be shown that Czerny's results gave a balance in favor of the operation, in supposedly suitable cases, it far from follows that less experienced operators, in such a grave and comparatively difficult operation, would obtain like good results. Indeed, if one may judge from isolated instances recorded—results argue rather against than for the operation."

These opinions, as will be observed, are from English surgeons of international reputation, and, while they contain much wisdom, they are more conservative than the operators of this country or of Germany are willing to accept. While McCosh referred to the surgeons being in the transition stage nine years ago, to-day, with a technic nearly perfect, surrounded by all of the modern appliances which inventive ingenuity can devise in the line of preventing shock, hemorrhage, and the establishment of almost impregnable barriers against parasitic invasion, at the beginning of the twentieth century, we stand abreast with our brothers in the fatherland, ready to fight this foe of mankind when there seems to be any reasonable hope of conquering.

Erichsen[8] writes that removal of cancer by excision of a portion of the rectum was first performed by Faget in 1739. An inch and a half were removed and the patient recovered. Lisfranc revived the operation in 1826, reporting nine cases with five recoveries. In 1854 Chassaignac used the écraseur in the removal of rectal growths. Nussbaum and Volkmann, in Germany, and Jordan, Allingham and Holmes, in England, worked diligently toward reviving the operation. The surgery of the rectum was developed and brought up to date in 1880 by the publication of Harrison Cripps' interesting work.

Gerster[9] wonders that any surgeon should have had the temerity to attempt to remove any extensive rectal neoplasm after looking into the imperfect and therefore bloody and dangerous procedures devised by Dieffenbach, Velpeau and other early operators.

Stanley Boyd's[10] edition of Druitt's *Vade Mecum* as late as 1887 refers to the high death-rate and sepsis is put down as the chief cause. The mode of approach was primitive, the hemorrhage was inevitably profuse, owing to the limitation of the field of work and the inaccessibility of the pelvic basin and its diseased contents (Gerster).

In 1883 while Richard Volkmann was removing a malignant growth from the sacrum, by accident he opened the sacral canal. This misfortune resulted in no untoward symptoms for the patient, and this fact aroused Kraske, who was then an assistant in Volkmann's clinic. The experimental research along this line led to the publication in 1885 of Kraske's[12] monograph, which revolutionized rectal surgery, reducing, as it did, the mortality after excision from 57 per cent. (Iversen) to 19 per cent. (McCosh).

Kraske's Method.—With the patient on the right side, a median incision is made, extending from a point opposite the third sacral foramen to the anus. After thorough retraction of the soft parts, the great gluteal muscle is loosened from its sacral attachment. The coccyx is removed and the lower fibers of the sacrosciatic ligament are divided. With a chisel, the left half of the lower part of the sacrum is removed as far as the pelvic floor, making easy access to the diseased cylinder and its adjacent parts. A collection of 102 cases operated upon in this way gives a mortality of 21.5 per cent., though Thorndyke's collection of cases gives a mortality of only 14.7 per cent. (Warren.[27])

The upper limit of the bone incision in all sacral

operations is explained lucidly in Dr. McCosh's paper, read before the New York Surgical Society April 13, 1892,[13] in which he says: "Division of the posterior branches of the sacral nerves is of little moment, as no important tissues are supplied by them. Division of the anterior branches of the fifth nerve is also unimportant. Division of the anterior branches of the fourth nerve, if confined to one side, is not followed by serious disturbance. Division of the anterior branches of the third nerve should be avoided, as they enter into the formation of the ischiatic plexus and serious changes in the innervation of the pelvic organs are liable to follow injury of either of these branches."

Bardenheuer's Method.—With the patient in the lithotomy position, the skin incision is practically the same as Kraske's, but the sacrum is cut transversely below the third sacral foramen and removed with the coccyx.

Heinecke's Method.[15]—Wishing to avoid whatever tendency toward weakening the pelvic floor which Kraske's method might bring about, Heinecke devised in 1888 a T-shaped incision in the skin, sawing the sacrum first vertically and then at the level of the fourth foramen transversely, thus making two folding bone doors. These are afterward united by suture.

Kocher Method.[16]—A long integumentary incision is made, freely exposing the bone. With a chisel each side of the sacrum is grooved along the inner side of the foramina, beginning at the third. The segment which is called the *"knochenspange,"* is removed. This exposes the sacral canal and makes certain the protection of the nerves.

These last two methods seem too complicated to have received general indorsement, yet the lateral blood-supply is maintained in both.

Levy,[17] in order to spare the fourth sacral nerve and the levator ani's coccyeal insertion, suggested an incision shaped like an inverted letter U, bending the osteoplastic arc toward the anus. But because of the limited space it offers, and the very imperfect drainage, it has seldom been used.

Hegar[18] carried the knife along the sides of the sacrum, making a letter V, and hinges the flap with a chain saw. Gerster claims good drainage in this method, but condemns it because of the impairment of the flaps' vitality.

Hochenegg[19] made a curved incision with the convexity to the right, commencing opposite the third foramen, extending outward and passing the middle line again below the last button of the coccyx. He based his report on thirty-two cases from Prof. Albert's clinic in Vienna.

Lange's[20] method of resection of the rectum with osteoplastic transplantation of the anal portion was brought to the attention of the profession at the meeting of the New York Surgical Society, January 14, 1891. Two patients were presented. In one a wide gap existed at the time of operation, between the proximal end of the intestine and the sphincters below, and it was to preserve the muscular power of the anus that led to the ingenious incision he then suggested. The knife was carried from each tuber ischii across the perineum in front of the sphincters. The incisions met in the raphe, and were made deep enough to allow of pushing the whole muscular apparatus of the anus upward, including the anal portion of the gut. Thus, in each case, fully three inches were gained and exact union of the gut with sutures to the sphincter was achieved. Dr. Lange recommends this operation where the sphincters can be preserved, and where the proximal end of the gut is not sufficiently movable to allow of its being pulled down to the anal ring.

Rehn (reported by Gerster) in 1890 described a series of successful cases in which a V-shaped incision was made, one leg of the V embracing the entire width of the sacrum below the third foramen, while the other passed along the left side of the sacrum and coccyx. This osteo-integumental lap when hinged exposes the diseased rectal cylinder in a most satisfactory way.

Zukerkandl, the Vienna anatomist, Borelias of Karlsbrona, and Wölfler, have reported modifications of Kraske's operation, each claiming special merit for his particular method.

Hartley[24] removed a cancerous mass complicating a rectosigmoidal intussusception according to a method suggested by Maunsell of Melbourne, Australia. The details of this method are unique and are described at length in the *New York Medical Journal,* October 22, 1892, also in Dennis' "System of Surgery," Vol. IV., p. 488.*

Dr. Howard A. Kelly describes the operation of drawing the proximal end of the sigmoid down into a slit which has been made in the closed rectal cylinder, clamping the traction sutures across the anus.

Dr. Charles K. Briddon[25] telescoped the proximal into the distal end of the gut in his classical case of complete, traumatic, transverse rupture of the rectum, and his patient made a good recovery.

Preliminary Colotomy.—This interesting subject can only be touched upon owing to the brevity of the time allotted to me. To those interested in this subject I would refer them to the scholarly articles by Dr Chas. K. Briddon in the *New York Medical Journal,* September 20, 1890, Dr. Robert F. Weir in the *Medical Record,* April 21, 1900, and more recently to Dr. Wm. J. Mayo's article in *American Medicine,* Vol. I., No. 3.

Dr. Briddon taught his students ten years ago that colotomy should precede proctectomy, and he almost invariably practised this teaching. Dr. Lewis S. Pilcher says, "preliminary colotomy is desirable in all cases; imperative when obstructive and ulcerative symptoms are marked." Dr. Wier writes that "the creation of a false anus is of increasing importance as a preliminary step in various operations on the rectum."

Bergmann[34] has not made a preliminary colotomy for some years. He claims that this opera-

* Maunsell's operation has recently been modified by Prof. Weir. The modification is a very ingenious one. Three cases are reported. MEDICAL NEWS, Vol. LXXIX. No. 4, p. 122, July, 1901.

tion does not ensure the emptying of the bowel. In 133 sacral operations by Hochenegg, reported by his assistant, Hanz Lorenz,[35] preliminary colotomy was done but four times. Notwithstanding the omission of this step in the preparatory treatment of the German surgeons, it is very frequently advocated and practised by American operators.

The operation is not entirely devoid of danger. Mayo lost his first case as a result of too much tension on the sigmoid, causing gangrene. However, it is so simple and safe in character that of itself it need not be considered as affecting the prognosis. It not only insures immediate relief of most of the distressing symptoms, the bleeding, the sacral pain, the tenesmus, thus permitting the patient to gather strength for the trying ordeal which is to follow, but it also insures the partial healing of the ulcer and diminishes the purulent discharge, to say nothing of the effective daily cleansing of the diseased tube which it allows in the preliminary treatment.

Report of Cases.—During the past year four cases of cancer of the rectum have come under my care. Two of these received operation and two were inoperable. Of the operated cases, in one a palliative colostomy for acute intestinal obstruction was done and in the second the Bardenhauer modification of Kraske's operation was employed.

Cases I. and II.—One from Triadelphia and the other from Bethany, W. Va., were admitted to my service in the City Hospital in Wheeling, suffering from inoperable carcinoma of the rectum. In neither case was it deemed wise to add the discomfort of an artificial anus; as there were no obstructive symptoms, moreover, this procedure could in no wise have checked the onward progress of the disease. Death came to the relief of both.

Case III.—Wm. B., aged sixty-seven years, living in Bridgeport, Ohio, I saw with Dr. Cole in April, 1900. Patient was suffering with symptoms of acute intestinal obstruction. He was admitted to the City Hospital, and under ether narcosis, in Trendelenburg position, a median incision revealed a cancerous mass, somewhat adherent, deeply situated and at the rectosigmoidal junction.

The critical condition of the man precluded the possibility of any prolonged plastic work. An inguinal colostomy was made. In five weeks the abdomen was opened a second time with the hope of doing a Maunsell operation, or some modification of it; but it was regretfully demonstrated that the case was entirely inoperable. The pelvic glands, mesentery and omentum were all matted together with cancerous adhesive infiltration. Recovery from the operation was satisfactory. The patient gained in flesh and strength, and at this writing, a year having passed, he is alive and fairly comfortable, with his artificial anus.

Case IV.—Carcinoma of the rectum, preliminary colostomy, excision of four inches of the gut, preservation of sphincter muscles, circular rectorraphy, complete recovery with restoration of sphincteric function. Mrs. K. F., aged 51 years, married, house-wife, no morbid family nor previous personal history. Increased difficulty and pain in effecting a bowel movement extending over six months, with the presence of blood, mucus and pus in the stools led to an examination November 11, 1900. There had been some tenesmus and the amount of blood lost was considerable; the dull wearing pain through the sacrum and bowel made her life a burden. There had been gradual loss of flesh and strength, and the cachexia early developed was now fastening itself upon her. The typical pipe-stem stools were in evidence.

The examination revealed an ulceration about one inch and a half from the sphincter, extending along the posterior wall of the rectum. This, an inch and a half higher up, merged into a funnel-shaped, irregular stricture entirely encircling the bowel. The unguinal phalanx passed with difficulty beyond the constriction, causing much pain and rather copious bleeding. The uterus could be made out above the cicatrical narrowing and there was healthy gut beyond this point.

Operation was honestly placed before the patient, with its many risks, the possibilities of relief, and prolongation of life or even of a permanent cure, and it was accepted. The patient was immediately placed upon preliminary treatment. Intermuscular inguinal colostomy was done December 5, 1900. The colon was easily recognized by its anatomical peculiarties, and brought into the wound. Traction was made in the direction of the descending colon, and continued until shortness of the mesocolon arrested further extension. This step in the technic is of the greatest importance, preventing beyond doubt procidentia through the newly-made anus.

The writer cannot agree with Wyeth, as reported by Mayo, when he says: "All of the movable sigmoid should be pushed upward, making the opening as near the rectum as possible." The sigmoid flexure may be the natural reservoir for fecal accumulation, but by placing it on the proximal side of the new anus, prolapse will most certainly occur in some cases. Having had one experience of this kind, the writer does not hesitate to place emphasis on this point, so well set forth in Dr. Pilcher's article.[37]

The protruding colon was withdrawn far enough to expose the mesocolon, and a supporting rod of glass about the thickness of a slate pencil was thrust through the mesentery. This clean rod at once created a spur, preventing the return of the gut and holding the parietal and visceral peritoneum in contact. No sutures were used. Three days later the bowel was opened with a Paquelin cautery. Irrigations of the colon and a cleansing toilet of the rectum were practised once or twice daily until the day of the sacral operation.

Operation was performed December 18, 1900; ether narcosis; Sims' position. An incision was made from the middle of the sacrum to the anus. The coccyx was removed and the sacrum divided

transversly just below the third sacral foramen with a chisel. The sphincters were divided, the rectum laid open posteriorly, a circular incision was made a half inch above the sphincter entirely around the gut, and the blunt dissection pushed forward. The liberation of the diseased tube was not difficult. The dissection was carried an inch and a half beyond the disease, and the gut excised just below the point of the peritoneal reflection. The cut segment of gut above was approximated to the short remaining portion below, with as little tension as possible, and a circular rectorrhaphy performed. The divided sphincters were restored by the use of iron-dyed silkwormgut. A loose packing of sterile gauze was placed in the wide gaping wound. No iodoform gauze was used. While the patient's condition was good all through the operation, thanks to the skilled administration of ether by Dr. Robert H. Bullard, soon after reaching her bed she exhibited symptoms of profound shock; the skin was cold and clammy, the respirations were shallow and sighing, and there was no radial pulse. It required the most active measures, including the submammary infiltration of two quarts of decinormal salt solution to keep the heart beating, in addition to other cardiac stimulation.*

The progress of the case after the first forty-eight hours was uninterrupted. Her temperature was never over 99° F., and, excepting one small opening back of the anus, less than one-quarter of an inch in diameter, the new rectum never departed from the sphincters to which it was sutured. The wound granulated kindly, there was absolutely no infection. The artificial anus did most excellent work, permitting the cleansing of the bowel in both directions. There never was the least tendency to prolapsus. February 22, 1901, the artificial anus was closed, according to the extraperitoneal method suggested by Grieg Smith.

The patient has almost perfect sphincteric control. She has gained in flesh and strength, has lost her cachexia, and to-day is entirely well.

Revision of the Statistics.—During the past year or so a very large number of statistical papers have appeared on the radical operation for rectal cancer, based chiefly on the work done in German clinics. The majority of the latter have reported their cases so that we have a very complete account of what is going on in this department. Unfortunately it is not as easy as would appear to obtain accurate figures as to the sacral route. Some authors include under this title resection of the coccyx and temporary resection of the sacrum, while others do not. Naturally the precise route is not always mentioned. Some reports deal separately with intervention involving the bone, while others include under sacral the parasacral operation in which the bony structures are not divided. Authorities have different ideas of operative mortality, some including all deaths which follow the operation, others only such deaths as are caused directly by the latter. Many favorable percentages are, of course, due to the selection of cases, so that to-day no figures have any value which do not give the total number of cases which come to consultation. It is almost a rule in statistics that the greater the percentage of cases submitted to operation, the higher will be the operative mortality. Some authors compare the number of cures with the number treated, others with the number operated upon radically, others again with the number who survive the operation. There are thus three distinct standards, and more or less confusion is bound to arise. When all these sources of error and misunderstanding are borne in mind it will be apparent that the collection of accurate statistics under such circumstances is a difficult procedure.

Early in 1900 Krönlein[28] of Zurich compiled the statistics of clinics which had already published their reports for a period of years. Eleven large clinics were presented, including his own. His table shows that the operative mortality in radical operations of all kinds, irrespective of route, averages 19.4 per cent. He analyzes the causes of death in 161 cases. In a third table he shows that the permanent cures based upon the number of operations averages 14.8 per cent. Krönlein gives no statistics of the sacral route; his tables are full of interest and are as follows:

TABLE I.

OPERATIVE MORTALITY IN RADICAL OPERATIONS OF ALL KINDS.

Operators.	Year.	Operations.	Deaths.	Per cent.
Kocher	1873–1899	35	10	28.5
König	1878–1890	96	31	32.5
Czerny	1878–1891	109	11	10.
Krönlein	1881–1899	63	7	11.1
Gussenbauer	1882–1896	145	33	22.7
Bergmann	1883–1888	46	5	11.3
Madelung and Garre	1883–1899	53	10	19.
Kraske	1885–1896	80	15	18.7
Küster	1885–1898	95	24	25.2
Hochenegg	1887–1897	93	8	8.6
Mickulicz	1890–1897	66	17	25.7
	Total	881	171	19.4

The joint results as to the cause of death are as follows:

Number of deaths, 171—sepsis and pyemia, 46; peritonitis, 37; heart-failure, collapse, 32; pulmonary affections, 21; miscellaneous, 35.

Krönlein next compiles a table of permanent results, the period to include all patients who have passed three full years without any recurrence of the disease.

TABLE II.

PERMANENT RESULTS.

Operators.	Operations.	Cures.	Per cent.
Kocher	35	10	28.5
Czerny	109	16	14.6
Krönlein	63	10	16.
Bergmann	46	8	17.4
Madelung and Garre	53	6	11.3
Kraske	80	11	13.7
Küster	95	16	16.8
Hochenegg	93	12	12.9
Mikulicz	66	6	9.

Average percentage of cures, 14.8.

*The author desires to express his appreciation of the skilful services of Drs. J. Schwinn, Andrew Wilson and Wm. H. McLain and of the valuable pathological work of Dr. Wilson.

Aside from the foregoing, although three years' immunity is usually considered a cure, a number of late relapses have been recorded, as follows: Kocher, 3; Krönlein, 2; Kraske, 3; Hochenegg, 1; Mikulicz, 2; Madelung and Garre, 2; making a total of 13.

The general results, then, are as follows: Died from operation, 19.4 per cent.; permanently cured, 14.8 per cent.; balance, 65.8 per cent.

As to incontinence: Absolute continence, 30 per cent.; relative continence, 60 per cent.; incontinence, 10 per cent. These figures are based on the analysis of 39 personal cases of Krönlein.

Walter Christen, assistant to the Zurich surgeon, issued a paper at about the same time Krönlein's appeared.[29] Christen's paper deals entirely with Krönlein's personal cases, private and public. Out of 46 cases seen 24 received radical operation and of this number there were two deaths, a mortality of 8.3 per cent. Fifteen patients underwent relapse sooner or later. The 15 cases of relapse averaged twenty-seven months of life, while the non-operated cases averaged but eight months.

About the same time there was published by F. Schneider[30] the statistics of the Rostock clinic representing the work of Madelung and Garre. One hundred and fifteen patients applied for treatment for rectal cancer from 1883 to 1899; of this number 53, or 47.2 per cent., were subjected to radical intervention. Kraske's operation was done fourteen times, resection of the coccyx alone twelve times, and temporary resection of sacrum by Schlange's method four times, making a total of 30 bone operations, with an operative mortality of 25 per cent. Only two survivors passed the three-year limit; one is still well, while the other had a relapse after six years.

Up to this time we find no satisfactory statistics of the sacral operation. Early in 1900 Josef Pichler, assistant of the Vienna surgeon, Prof. Hochenegg,[31] collected for the first time all of the sacral cases he could locate, in which the operators had a series of operations to their credit, including a small number of miscellaneous operations once collected by Frank.

TABLE III.

PICHLER'S TABLE OF SACRAL OPERATIONS.

Source.	Cases.	Deaths.	Per cent.
Czerny	36	7	19.1
Krönlein	1	1	
Mikulicz	57	14	24.5
Frank (miscellaneous)	39	7	17.9
Vienna Hospitals	83	13	15.6
Bilroth Klinik	56	10	20.4
Gussenbauer	15	4	26.6
Klausner	5	0	0.
Kraske	66	5	7.5
Paul	19	4	21.
Swinford	14	2	14.
Regnis	4	1	
Küster	46	7	15.2
Hochenegg	119	6	5.04
Total	563	81	15.

The Rostock cases reported by Schneider which would increase the number to nearly 600, are not included in this table. It might be well to mention as a comparison a collection of 217 cases of perineal operation from the statistics of Czerny, Kocher, Krönlien, König, Mikulicz and Gussenbauer, containing 37 fatalities, or 17 per cent.

Hochenegg's 119 sacral cases are carefully tabulated in Pichler's article, and of this number 29 were living three years after intervention. Of the 40 out of the 119 cases known to have relapsed, the average duration of life was 21.4 months.

Upon the appearance of Pichler's paper, Prutz of Königsberg, assistant to Von Eiselburg, attacked[32] the statistics and revised them or edited them in such a way that he made the operative mortality 21 per cent. instead of 15 per cent. for the sacral method. Prutz includes all deaths indirectly due to operation, while Pichler takes the direct deaths only. Soon after this controversy Prutz wrote a second paper,[33] which was a study of Von Eiselburg's cases of rectal cancer and these are not included in any of the preceding tables. During the years 1896-1901, 75 cases of cancer of the rectum came to the Königsberg clinic for treatment; the proportion of men to women was 10 to 7. Forty-five cases underwent operation, or 3 out of every 5, and 38 of this number were sacral cases. The operator lost 5 of his 45 cases, making a mortality of 11.1 per cent.

It will be seen that in Krönlein's table Bergmann's statistics extend only to 1888, while Pichler's sacral table contains no reference to Bergmann. After the preceding papers had called attention to the matter Heinrich Wolff, assistant to Von Bergmann of Berlin,[34] published all of the latter's material from 1888 to date. The total number of cases seen was 155, of which 125, or 80.6 per cent., were subjected to radical intervention, while 30 were treated by palliative measures.

Amputations: Extirpation of coccyx alone, 21 cases; extirpation of coccyx with partial restriction of sacrum, 8 cases; no bone operation 17 cases; data wanting, 14 cases. The operative mortality in 60 amputations was 9, or 14.7 per cent. Of 39 survivors followed up 12 are still living. Of 65 resections only two were operated upon by other than the sacral method, and in these two an abdominal section was performed. Of the whole number of resections, 31 died as a result of operation, 47.7 per cent., and of 34 survivors 28 were followed up, and of this number 8 are still alive.

Combined statistics: In 125 operations there were 40 deaths, 32 per cent. mortality. One-half of these patients died from collapse, narcosis, hemorrhage and shock. Permanent cures from both operations, 27.7 per cent.

Wolff points out that any attempt made to demonstrate the excellence of highly-individualized methods of operating have a tendency to injure statistics by making comparisons difficult. Another fallacy is found in the selection of only simple cases for operation, which naturally gives

a low primary mortality. As a result of his study of statistics he notes the great discrepancy in the results adduced and seeks to explain them on one of two grounds, namely, the fixation of the indication *before* operation or the fixation of the indication *during* operation.

The author is able to demonstrate his points from two sets of statistics in Bergmann's clinic. The first series runs from 1883 to 1888 and has a primary mortality of 11.3 per cent.; the second series extends over the period 1888 to 1900, with an operative death-rate of 32 per cent. These results were obtained in one and the same clinic, and by the same operator. We can therefore do away with matters of personal equation, such as differences in technic and of material seeking operation.

To explain such wide discrepancies, however, there must be some reason. The modern methods of wound treatment may have its weight, or the indications for interference may have undergone change. Certainly the results obtained during the second statistical periods were three times as bad as during the earlier epoch. Why? The chief explanation which can avail here is that the surgeon, in later years, began to operate on cases which he had previously regarded as inoperable. But this course of reasoning does not exhaust all the possibilities. Examination during narcosis, a step, by the way, which should never be omitted, may also exert a strong influence on the issue of the case. The revelation of extensive adhesions or glandular involvement must often cause the operator to change his original plans, if he has his patient's interest at heart. Two courses are open to him: First, he may abandon further intervention, may change a would-be radical to a palliative procedure, thereby saving the sufferer from operative death, while placing him in line for certain relapse, and thus obviously benefiting statistics. The second course is the extremely radical one, the extirpation of the infected ganglia and adhesions, placing the patient's life in extreme jeopardy—this same patient who would have been satisfied had the operation been abandoned and would have lived to thank the operator.

For many years Von Bergmann has advocated and used the sacral method for cancer high up in the rectum, and he has also used the modification known as the Schlange osteoplastic operation. While this latter modification gives better access to the tumor than any other method, it is undeniably formidable and is attended with excessive hemorrhage and shock.

Amputation of the rectum is attended by considerably less danger than is resection; so much so that statistics of the two operations should be kept separate. Amputation is less bloody and requires less time. Opening the peritoneum is no longer regarded as a momentous complication. Most operators will share this opinion with Wolff, yet it should be avoided, particularly in resection cases in which a preliminary colostomy has not been done. Wolff speaks of the importance of eight or ten days of preparatory treatment, or even more. Only liquid nourishment is allowed during this period, and stools are secured regularly by the use of castor oil and enemata of water. Hochenegg and Lorenz[35] express the very opposite opinion, claiming it is difficult to empty the bowel when a stricture of the gut exists. The fluid dejecta produced by purgatives may do more harm in premature defecation than if the feces are scybalous. The Vienna surgeon has therefore abandoned purgatives on this account.

In the treatment of the wound surface Bergmann abstains from a primary suture and relies upon tampons of iodoform gauze. In a certain number of cases Wolff describes a delirium which followed the operation, lasting two or three days or as many weeks. This was thought to be due in a measure to iodoform toxemia and simple sterile gauze was used in its stead in a series of cases. Nevertheless the delirium still appeared with some frequency. According to some authorities, this delirium is apt to follow rectal operations, which perhaps justifies the belief that the phenomenon is due in some way to the bacillus coli. In this connection it will be well to mention that the liberal use of iodoform gauze in large gaping wounds of the kind under consideration is undoubtedly pernicious. Sterile gauze will answer the same purpose and its use is attended with no danger.

One word regarding the *"durchzeit"* operation recently described by Hans Lorenz.[35] Of the 133 sacral operations performed in Hochenegg's clinic, bringing this operator's work up to February, 1901, there were 90 amputations, 25 resections and 17 of the so-called *"durchzeit"* operations. This latter method, devised by Hochenegg seeks to substitute for reuniting the intestine a suture of the bowel to the lips of the skin.

The mortality of the three forms of operation is as follows: Ninety amputations with 13 deaths, of which 8 were from wound infection; 25 resections with three deaths, all from wound infection; 17 *"durchzeit"* operations with one death from wound infection. In all cases in which the sphincter is left intact after excision of the rectum, and in which it is possible to mobilize the proximal end of the gut without serious tension to the sphincter, Hochenegg adopts this method. He denudes the mucosa and inverts the anal portion, then brings down the proximal gut and sutures it to the external skin.

The functional result following the *"durchzeit"* operation is interesting and is shown in the subjoined table.

TABLE IV.

Result.	Durchziet Method.	Resection.
Complete Continence.....	47 1–17	36 4–11
Partial Continence.....	29 7–17	27 3–11
Incontinence.....	23 9–17	36 4–11

The latest clinic to make a complete report of its work is that of Schedé of Bonn, reported by Carl Vogel[36] in April, 1901. Schedé has performed 22 sacral operations with 10 deaths, while

TABLE V.

VOGEL'S MODIFICATION OF KRÖNLEIN'S TABLE I. BROUGHT UP TO FEBRUARY, 1901.

Operator.	Mumber treated.	Radical Operation.	Mortality.
König	120	78.3 per cent.	32.5
Czerny	151	71.1 "	10.
Krönlein	110	57.2 "	11.1
Gussenbauer	259	56. "	22.7
Von Bergmann	155	80. "	32.
Madelung and Garre	115	46. "	19.
Kraske	110	73. "	18.7
Küster	126	75.4 "	25.2
Hochenegg	141	66. "	8.6
Mikulicz	109	66. "	25.7
Helfenit	46	48. "	13.6
Schedé	66	80.3 "	32.
Total	1508	66	20.

his percentage of recoveries is 25 per cent. Vogel concludes his paper with the following interesting table, modifying Krönlein Table I. by additions.

SUMMARY OF SACRAL OPERATIONS.

	Cases.	Deaths.	Per cent.
Pichler	563	81	15
Prutz (revision of Pichler's)	542	115	21

Since the controversy over these statistics the following have appeared:

Rostock Clinic	32	8	25
Von Eiselberg	38	?	?
Von Bergmann	92	?	about 45
Hochenegg (up to Feb. 1901.)	14		
Schedé	22	10	45
	198		

These cases add nearly 200 more sacral operations to the material collected by Pichler, or a total of 761 sacral operations for cancer of the rectum for Germany, Austria, and Switzerland, with a few in the British Islands, with an operative mortality of about 18 per cent.

THE PROBLEMS OF PHYSIOLOGY AND PATHOLOGY.[1]

MARTIN H. FISCHER, M.D.,

OF CHICAGO;

PATHOLOGICAL LABORATORY, RUSH MEDICAL COLLEGE, CHICAGO.

THE problem that most interests scientific medicine to-day is the nature of life phenomena. The methods of work and reasoning which the past has applied to the solution of this problem have failed of that complete explanation which we crave. It seems evident, if we interpret the signs of the times correctly, that medicine is undergoing a radical change and that it is approaching its great problem from another standpoint than that of the past. Within the last few years physics and chemistry have made advances of a most signal nature, and it is to the application of these newly-learned truths to the problems of medicine that we must attribute the changes that modern medicine has undergone. Indeed, to bring medicine under the rigid laws of physics and chemistry seems to offer the only hope of establishing it as a science, and of depriving it of those characteristics which have led some men, alas, to call it an art. Deeply hidden as seems to be this essence of organic nature—life, our craving for the knowledge of the unknown will give us no peace until we have found it. How near at hand or how distant the solution of this problem may be is not for us to say. Every day brings some new fact to light that carries us a little nearer to the solution of our world enigma, and so long as this continues man will not cease in his endeavor to know still more.

In the following pages I have collected a few of the facts which show what the present is contributing to the solution of our problem. I have confined myself to the fields of physiology and pathology, and it has been my object to show where it is possible that the answers to some of our questions lie.

For years men have toiled in the department of anatomy and by description and drawing have given us an insight into the architecture of the body. With the invention of the microscope, and

[1] An address delivered to the graduating class of Rush Medical College, Chicago, June 20, 1901.

the development of the cellular hypothesis, our knowledge in this direction has been much refined, and with modern facilities this knowledge has become so widespread that every student of medicine has in his possession a clear picture of the machine with which he has to deal. This has helped much in the elucidation of life phenomena. Pathology, of much more recent date, has had the same developmental history. Just as we have had a cellular physiology we have had a cellular pathology. But morphology has its limits and description and illustration have an end. The close of the last century has perhaps seen the last of the great contributions that morphology can make to medicine. Much as this morphology has added to the knowledge of the structure of our machine, it has given us but little insight into the forces that operate it. And so it is that we have been driven to look to that which lies behind structure, to a consideration of the composition of the substances that go to make up the outward form. We have been forced to abandon the fields of morphology and to enter the domain of chemistry.

But let me not be misunderstood. The necropsy theater has been the means of linking together signs and symptoms with definite pathological lesions. The accuracy of our present medical diagnosis is but the expression of careful clinical study followed by patient postmortem investigation. The value of histological pathology, too, in its bearing upon clinical medicine can never be overrated. The microscope has been and must ever remain one of our most trustworthy aids in the diagnosis of many obscure pathological conditions. But the diagnosis of diseased conditions is not the ultimate object of medicine; medicine would do more than this —it would control the forces of which pathological lesions are but the outward expression. Clearly morphology can render us little service in this direction. My remarks have reference to the future in pathological research.

* * *

The physiologist's problem of to-day is the determination of the constitution of living matter; the pathologist's problem, the constitution of living matter in its perverted state. For years physiological chemistry has busied itself with a study of the chemical processes that go on within the living organism. It has studied the substances necessary for the metabolism of the animal tissues and the end-products of this metabolism; it has studied the ingesta and the egesta of animal economy. The same statement holds for pathological chemistry. Only recently has the question been asked, "What happens between the beginning and the end of metabolism?" And it is just here, in this study of what we might call dynamic chemistry, that the solution of so many problems in physiology and pathology lies.

It is now about fifteen years since physical chemistry—the science which would point out the relation between the physical properties of a substance and its chemical constitution, the science that deals with the dynamics of chemistry—was established as an independent science. Time does not permit me even to mention the rich results that this new science has already yielded, and the purpose that it has served in the elucidation of many obscure chemical and physical facts. What is thus far one of its greatest developments, the theory of electrolytic dissociation, has in itself served to correlate a mass of heterogenous facts which seemed to bear no relation whatsoever to each other. What the possibilities are that lie in the application of this theory to the problems of physiology and pathology may be imagined after a brief recital of a few of the facts that such work has already yielded.

When the gastrocnemii of frogs are immersed in equimolecular salt solutions, it is found that the amount of water absorbed by them depends upon the nature of the solution in which they are immersed. In solutions of sodium or lithium salts the muscles gain but little in weight; in equimolecular potassium salt solutions the increase in weight is enormous; in the equimolecular solutions of a calcium salt the muscle loses water. Furthermore, the coagulation of albumin by heat is intimately associated with the presence of inorganic salts. Experiments with equimolecular salt solutions show that the point of coagulation of a salt-albumin mixture varies with the nature of the salt employed. These and other facts seem to indicate that the various salts in the body probably stand in definite combination with the proteids as ion proteid compounds. It is possible to substitute one class of ions for another, and so alter the chemical and physical properties of the proteid molecule. With alterations in physical structure come alterations in function. To supply an organism with only one salt is to destroy its function. Thus, even common salt, sodium chloride, which permeates all our tissues, in pure solution acts as a poison, since it supplies the organism with only one kind of metallic ions.

The riddle of the heart beat, too, has been brought a step nearer solution. It has been definitely proved that the rhythmic activity of the heart is dependent upon the presence of certain salts in the blood. The heart cannot beat except in the presence of sodium ions in the circulation, but sodium ions alone act as a poison and soon bring the heart to a standstill. The presence of certain other, for example, calcium ions, however, neutralizes the poisonous effects of the sodium ions. Indeed, in a mixture of these two salts heart muscle will beat rhythmically for hours. Any of the voluntary muscles can be made to contract rhythmically just as heart muscle by the simple abstraction of a little calcium from the mixture of these salts. It is a slight excess of calcium in our blood that keeps the voluntary muscles of our bodies from contracting rhythmically. These facts are interesting in another direction; they show that in this case chemical and not morphological differences underlie variations in function.

In the physiology of taste, the theory of ionization has also correlated many heterogeneous facts. Acids taste sour because they contain hydrogen ions; the characteristic taste of hydroxides is due to their hydroxyl ions. With inorganic compounds the intensity of the taste is directly proportional to the number of ions that the solution contains. With organic salts, however, this law does not hold. The halogens have a salty taste due to the halogen ions. Sodium, potassium, magnesium, lithium, and other metallic ions each have an individual taste. Thus the taste of a given salt is dependent upon the nature of the ions that constitute its molecule.

The application of the theory of electrolytic dissociation to the action of germicidal solutions has forever laid to rest the old idea that the action of a mercurial is dependent upon the amount of mercury contained in solution, and is independent of the nature of the compound. The germicidal action of a mercurial is dependent upon the number of mercury ions in solution, and since among the mercurials the bichloride dissociates most readily when dissolved in water, it has the strongest antiseptic action. That it is, indeed, the mercury ions that are the efficient agents in the destruction of bacteria is proved by the fact that the solution of a mercury salt in alcohol—a substance in which no electrolytic dissociation occurs—has no germicidal properties. The same reasoning is applicable to the salts of silver, gold, zinc, copper, and the other metals.

Pathologists have in years past sought the explanation of the edema which occurs in some pathological processes either in an increased blood-pressure, or in changes in the permeability of the vessel-walls, which under normal or increased blood-pressure permit the blood serum to filter through. Thus the cells concerned in the edematous process have been considered to play only a passive rôle. There are facts, however, that go to show that the cells play an active part in the pathological process. I have already referred to the experiments which show that the differences in the constitution of protoplasm which follow its immersion in various equimolecular salt solutions lead to differences in its ability to absorb water. It is not impossible that the conditions which give rise to the edema may in reality so disturb the normal metabolism (through lack of oxygen or altered processes of fermentation) as to lead to an increase in the number of molecules in the cell, or to changes in the chemical constitution of the protoplasm. This places the cell in a position to absorb water from the blood or lymph. Thus an edema of the affected cells results.

The mechanical notion that a cell may be considered a semipermeable membrane enclosing protoplasm has been much neglected. It has been known for many years that certain vegetable cells, when placed in water or in a solution of less concentration than that contained in the cells, swell up and burst. To van t'Hoff belongs the credit of having pointed out that in this case we are dealing with differences in osmotic pressure between the cell-contents and the surrounding fluid. The semipermeable membrane separating the two fluids is found in the layer of protoplasm which lies close to the inner side of the cell-wall. This mechanical conception of the cell and its bearing upon osmotic phenomena is not to be lost sight of when we look for the explanation of life phenomena along purely chemical and physical lines.

Another field that promises great contributions to physiology and pathology is the study of enzyme activity. Enzymes are characteristic of all life phenomena, pathological as well as physiological With the ordinary properties of enzymes, their ability to produce change in other substances without undergoing change themselves, their power to bring about this change independently of the amount of the ferment employed, their destructibility by heat, most students of science are familiar. Recently it has been found that the action of certain enzymes is reversible. This gives the enzymes an entirely new rôle in the explanation of life phenomena, for they can no longer be considered as substances which have to do only with the breaking down, but also with the building up of complex molecules.

Lipase (steapsin) the fat-splitting enzyme of the pancreatic juice has the power not only of dissociating a fat into its fatty acid and alcohol, but also of building up fat from a mixture of fatty acid and alcohol. Which of these two functions it is that lipase manifests is dependent upon the relative proportions of fat and the products of dissociation that are present; in other words, lipase establishes a chemical equilibrium between the fat, and the fatty acid and alcohol. Outside of the body, fat is digested by lipase only to a certain extent if the products of enzyme activity are not removed. This is because a state of equilibrium is reached between the molecules of fat and the products of its dissociation. If, as in the intestine, the fatty acid and alcohol are removed as soon as formed, the fat-splitting ferment continues its action until all the fat is digested. Of what significance, now, is the reversibility of this enzyme action? Simply this. The presence of lipase has been demonstrated in the various regions of the body where fat deposits are found. As the fatty acid (this circulates in combination with the salts of the blood as a soap) and the alcohol come into contact with the enzyme of the cells, since there is now an excess of the fatty acid and alcohol, the enzyme activity is reversed, and fat is deposited. The fat absorption which occurs in starvation is also readily explained by the reversibility of the fermentative action of lipase. In starvation the fatty acid and glycerin of the cells diffuse into the blood. In consequence the equilibrium existing within the cells between these substances and the fat is disturbed. This causes the lipase to reverse its action, and where its presence once led to the building up of fat, it now leads to fat destruction.

The action of maltase, a ferment found in the

saliva, is also reversible, for not only can this enzyme split up a molecule of maltose into two of glucose, but it can build up two molecules of glucose into one maltose. Which of these takes place is simply a matter of equilibrium, for in the presence of an excess of maltose the enzyme forms glucose; in the presence of an excess of glucose the enzyme forms maltose. It is possible that the action of the proteolytic enzymes is also reversible. If this be true then the long debated question of how the body is able to build up proteids out of the products of proteid digestion is at an end.

Physiologists have long been troubled to explain the relation of the breaking-down processes which occur in digestion to the building-up processes which go on in the tissues. The reversibility of the action of enzymes shows how it is possible to build up complex molecules from the simple molecules which are the products of digestion. This makes the changes in digestion and tissue metabolism the same.

* * *

It would scarcely seem necessary in the present state of scientific development to speak a word against the "vitalistic" tendencies of certain classes of scientific workers. One would think that the search for causality would prevent scientific men from having recourse to the teleological in the explanation of life phenomena. Allowing for the moment that the position of these observers is the correct one, we, in our attempt to solve the problems about us, can never admit it. Such views lead only to scientific stagnation. To say that "Nature" is responsible for the hypertrophy of the blacksmith's arm, or that "Nature" causes the hypertrophy of the heart in a pregnant woman, illy answers our ever-pertinent question, "Why?" We are inclined rather to look for the explanation of these phenomena in the altered metabolism of the muscular structures. It is not "Nature" that causes the caterpillar to go up the tree in search of food; it is the animal's response to light (heliotropism), a response as definite when dry branches and death await the animal's arrival at the top, as when young shoots and life crown its efforts.

Let us pause for a moment to ask ourselves whence the assumption of a vital force comes. The old philosophers and physicians found all life phenomena intimately associated with a "spirit of life." Hippocrates, Erasistratus, Democritus and Galen could explain locomotion, respiration, speech, and the beat of the heart only through the existence of their *pneuma*. This philosophy continued until the fifteenth century, when, with the discovery by Harvey of the circulation of the blood, the superstitions that had for so many centuries enveloped the manifestations of what we term "life" received a severe rebuke. The circulation of the blood, together with the study of respiration, seemed to make possible the explanation of at least some life phenomena upon purely mechanical grounds. Deeper studies into the interchange between oxygen and carbon dioxide, and studies into the phenomena of digestion showed that other life processes are explainable upon a purely chemical basis. On the other hand, a great number of physiological processes continued to baffle the human mind. The physiologist Haller, who in his *Elementa Physiologiæ* first collected the discoveries in physiology that followed Harvey's work, failed to see how the "sensibility" of nerve or the "irritability" of muscle could be explained upon any other ground than the assumption of a specific *vis vitalis*. Still more baffling were the phenomena of reproduction and mental activity—two processes so obscure and so enveloped in mystery that a purely mechanical explanation of them seemed impossible. It was thus that a complete dualism in physiology sprang up, for while the explanation of some life phenomena upon a purely chemical and physical basis seemed possible, that of others was possible only upon the assumption of a vital force. These views were, however, but little better than the superstitions that had so blinded the progress of science before the days of Harvey.

It is to Helmholtz, Ludwig, Brücke, and others that we must give the credit of being the first to rebel against the vitalistic explanation of life processes. These thinkers showed that most of the phenomena that occur in the human organism take place in accordance with simple physical and chemical laws. I need not here recite the progress in physiology and pathology that the last half century has yielded. We no longer call upon a vital force in the explanation of the gross manifestations of life. Modern vitalists become so only when the functions of the individual cell are concerned. Modern dualism is the dualism of centuries ago, only with the advance of the ages it has undergone a refining process. Let it be noted that vitalism begins in every case where definite knowledge ends. Ignorance of the common laws of physics and chemistry made vitalists of the ancients; while our temporary ignorance of the physics of the colloidal solutions, and of the complex chemistry of the proteid molecule, makes vitalists of some physiologists and pathologists of to-day.

Each year brings new facts to light that contribute to the explanation of normal and abnormal life processes upon purely physical and chemical grounds, while they correspondingly detract from the value of all vitalistic explanations. Mental activity is no longer considered the expression of a disembodied spirit, and modern students of physiology cannot conceive of a mental act which has not its organic basis. psychology is an experimental science and as such is fast taking its proper place as a subbranch of physiology.

Enzyme activity which underlies all life processes is also associated with naught that is vital. The famous controversy between Pasteur and Liebig as to the vital principle concerned in fermentation is forever at an end. We now know that the enzyme activity of various organisms is dependent upon the presence within them of cer-

tain chemical substances that can be extracted from the dead calls, and which when added to fermentable substances produce chemical changes in them in just as typical a way as the organisms themselves. Zymase, the enzyme contained in yeast cells, is just as capable of splitting sugar into carbon dioxide and alcohol as the yeast cells themselves. In our own cells the processes of oxidation, so essential to and so characteristic of life, are dependent upon certain enzymes. But there is nothing living or vital about them, for they can be extracted from dead, even from alcohol-preserved tissues, and will when added to certain substances oxidize them in as characteristic a way as ever oxidation occurred in the living animal itself.

It may not be out of place for me to digress a moment in order to cite an experiment which shows how the action of these oxidizing ferments may be mimicked in the laboratory. It is possible with proper laboratory facilities to suspend finely-divided metallic platinum in water. This colloidal solution is capable of reducing hydrogen peroxide in just as characteristic a way as are the ferments derived from organic sources. The addition of hydrocyanic acid to these oxidizing ferments inhibits their action. In the same way the addition of hydrocyanic acid to the colloidal solution of platinum inhibits its power of decomposing the peroxide of hydrogen. Thus we have the paradox of being able to poison or "kill" a dead substance.

The phenomenon of reproduction, too, has been deprived of its vitalistic nature. The last two years have shown that a slight abstraction of water from the eggs of certain marine animals causes them to develop into living, swimming embryos without the intervention of the spermatozoon. Residence for a few hours in a concentrated solution of sugar, urea, glycerin, or any one of several salts brings about the necessary abstraction of water from the unfertilized eggs, which when returned to sea-water develop parthenogenetically. In some varieties of marine life the fertilizing function of the spermatozoon is replaceable by the addition of certain ions to the sea water. A few drops of acid, or the addition of a small amount of any potassium salt causes the development of embryos from the unfertilized eggs of the sea-worm *Chætopterus*. Thus is done away with the specific "life-giving" power of the spermatozoon. The development of embryos from unfertilized eggs which under ordinary circumstances cannot develop without the intervention of the spermatozoon breaks down another barrier to the explanation of life phenomena upon a purely physical and chemical basis. These experiments serve to show the weakness of the vitalist's position. The scientific worker of to-day must consider life as the expression of certain chemical changes that occur in the organism. Never can he consider chemical change as the expression of the specific "life" residing within the cell.

***

I believe that the few facts which I have brought to your notice this afternoon suffice to show that the progress of science toward the solution of our world problem, life and its manifestations, lies along chemical and physical lines. It is my firm belief that with the close of the nineteenth century the curtain has practically fallen upon cellular physiology and cellular pathology. The new century has to busy itself with a *molecular physiology* and a *molecular pathology*. Physical chemistry will serve no small purpose in solving the problems that confront us. The study of enzymes, too, will answer some of our questions. It is essential that we lay aside our tendencies toward vitalism. Vitalism is an unknown equation and serves only as a cloak for our ignorance. The argument that we are unable to explain all life processes by simple physical and chemical laws and that in consequence we must assume a "vital force" is as indicative of ignorance as it is of weakness. Let it not be forgotten that chemistry and physics have not yet solved their last problems. Until recently physicists have considered all matter to be composed of atoms and molecules. Physical chemistry has added a third form of matter, the electrically charged atoms and groups of atoms called "ions." A fourth form of matter, the "electrons," dates from the discovery of the Roentgen rays. In the face of the fact that the physicist has not yet determined the constitution of matter, it is irrational to expect the physiologist to be acquainted with the constitution of living matter. Time will solve all problems. In the meantime let us cultivate our demand for causality, and let us be satisfied with no explanation save that of experimental proof.

INTRATRACHEAL INJECTIONS IN BRONCHIAL AND PULMONARY AFFECTIONS.

BY WILLIS S. ANDERSON, M.D.,
OF DETROIT, MICH.;
LARYNGOLOGIST TO THE HARPER HOSPITAL POLYCLINIC; ASSISTANT TO THE CHAIR OF LARYNGOLOGY, DETROIT COLLEGE OF MEDICINE, ETC.

THE inaccessibility of the lower respiratory tract and the belief that these membranes are too sensitive for local medication have necessitated that the local treatment of this region be largely by internal medication. Sprays are of value in the larynx and trachea, but do not reach the bronchi. Vapors and nebulæ penetrate the smaller bronchial tubes under favorable conditions, but the amount of the drug reaching the diseased part is so small that little benefit results.

Horace Green of New York is credited with being the first to use intratracheal medication. As early as 1838, he made applications of nitrate of silver to the trachea by passing a sponge saturated with the solution. He reported excellent results, but his treatment was considered too heroic to meet with general favor. The next step was the introduction of liquids into the trachea by means of a suitably-constructed syringe.

While this was practicable, and in skilled hands easily accomplished, the procedure was condemned by many, as the solution caused considerable irritation and coughing. Watery solutions with or without glycerin, and even mucilaginous solutions were found irritating. This method has met with greater success in the last few years, since it has been found that oily solutions of suitably-selected drugs are not irritating.

The writer believes that this method of treatment offers a valuable means of relieving many bronchial and pulmonary affections not readily amenable to ordinary medication. It seems rational that the same beneficial results which we are accustomed to get in treating mucous membranes generally should follow local medication of the trachea and bronchi. That this is true is amply proved by the systematic use of this method.

It is interesting in this connection to consider whether the normal mucous membrane of the respiratory tract is free from micro-organisms in health. Experimental observations, both in men and animals, indicate that the mucous membrane of the trachea and bronchi are sterile, or nearly so, and that the normal mucus of the bronchi, as of the nose, does not offer a suitable medium for bacterial growth. While such is the condition in health, in disease, micro-organisms of great variety and abundance are constantly found in the bronchi. Even in acute bronchitis micro-organisms have been found in abundance, and Ritchie from his experimental studies considers that this disease is infective, although not due to any single, specific organism. The organisms most commonly found were the diplococcus pneumoniæ and the streptococcus. The influenza bacillus appears to be frequently found in acute bronchitis even apart from epidemic influenza. Besides the above mentioned organisms, a number of others have been found occasionally. In chronic bronchitis and bronchiectasis, organisms are constantly found in the sputum.

In pulmonary tuberculosis, as long as the tubercle, with its specific germ, is alone present in the lungs, we have a condition which usually develops slowly. The patient has a hacking cough, slight fever, little expectoration, and few, if any toxic symptoms. If, however, the consolidated area becomes the seat of infection with organisms, such as the streptococcus or the staphylococcus, a different picture presents itself. The patient then gives distinct evidences of septic infection, high fever, night-sweats, abundant mucopurulent expectoration and breaking-down of the consolidated area. It is this secondary infection that adds so much to the gravity of the disease and is a condition difficult to combat.

It is possible by intratracheal injections to medicate the entire bronchial tree, and, by absorption through the lymphatics, to reach all portions of the lungs. Experimentally, it has been found that pigments are readily taken up by the pulmonary lymphatics, and, in man, we are all familiar with the mottled condition of the lungs, due to absorption of carbonaceous particles. By the intratracheal method from one to two drams of a menthol-guaiacol solution in oil can be introduced directly into the trachea without much discomfort to the patients. They can feel the solution in the bronchial tubes and the odor of the drugs can be detected in their breath for hours after the treatment. Some have said that they could taste the drugs in the expired breath for twenty-four hours after its introduction, indicating that the effect is more than a transient one.

In the congestive stage of acute bronchitis, the limited experience of the writer with this method of treatment would show that it is not adapted to this stage. It causes considerable irritation and possesses no advantage over the methods commonly in vogue. In the later stages of an acute attack where considerable thick, tenacious mucus is secreted, marked benefit will result from intratracheal medication. In chronic bronchitis it is of special value. Many patients whose digestive organs have been upset by ineffectual internal medication can be promptly relieved by this method. It quickly relieves the cough. At first, the expectoration of mucus is increased and rendered less viscid; after a few treatments the amount of the mucus rapidly lessens and with it the cough. In one case of bronchiectasis under the writer's care the mucopurulent expectoration cough and dyspnea rapidly decreased. The patient felt a decided relief after each injection, especially as regards the dyspnea.

As to its value in pulmonary tuberculosis, the writer feels that his observations have not extended over a sufficient length of time to warrant definite conclusions; but certain tentative deductions may be drawn from observed results. In the early stage when the infiltrated area was very small, when the afternoon fever was slight and the general nutrition not seriously impaired, it has seemed to be of benefit in lessening the liability to secondary infection and intercurrent attacks of bronchitis. In the second stage, when well-defined consolidation with bronchial breathing was present, and when secondary infection with its usual train of toxic symptoms was marked, decided and prompt benefit resulted from this method of treatment. Gastric irritation, which interferes with nutrition, frequently occurs in these patients from too active use of drugs.

This method offers us a means of controlling the local and general symptoms due to the pulmonary disorder, without recourse to internal drugging. It controls the cough more promptly than the usual methods and, though the expectoration is temporarily increased, the amount soon decreases and is more easily expelled. The fever and night-sweats decrease as the expectoration lessens and in proportion as the secondary infection is overcome. The dyspnea is improved and a general sense of relief folows its use. In the third stage, when the pulmonary tissue is rapidly

breaking down, when the cough, fever, night-sweats and dyspnea are marked, all that can be expected is a more or less temporary relief from the distressing symptoms. The writer does not claim any specific effect from this mode of treatment, but has seen marked and in a few instances permanent benefit in cases that have not done well under other methods of treatment. In all cases in which it has been used some relief has followed.

The results following its use in asthma are interesting and warrant further trial. This disease seems to be dependent upon many different factors, but from a practical standpoint we may consider it as a neurosis, with an exciting cause. We are also accusomed to divide our cases into the spasmodic and bronchial types. The value of intratracheal injections in the spasmodic type depends upon its power of relieving the acute symptoms and lessening the frequency of attacks. One case, that of a boy of fourteen, who for years had at night spasmodic attacks of dyspnea which were so severe as to prevent sleep, was markedly relieved by the intratracheal injections. The exciting cause in this case seemed to be in the nose and treatment was directed towards relieving the nasal obstruction. Before the nasal treatment was begun, the injections controlled the spasmodic attacks so that the patient could sleep all night, whereas before he was obliged to sit up several hours three or four nights a week. The correction of the nasal trouble has given him permanent relief, but during damp weather he occasionally has mild attacks, which are controlled by the injections.

Bronchial asthma is very satisfactorily relieved by the injections. The bronchial element, with the constant cough and expectoration is readily controlled, while the spasmodic attacks are lessened in frequency. In the case of a professional friend, who had bronchial asthma following an attack of acute laryngitis, the spasmodic attacks and dyspnea were relieved within a few minutes after the injection. In another case of bronchial asthma in an unmarried woman, aged twenty-eight, the benefit was marked. The patient gave a history of asthma and nasal trouble for two years. Her nose had been operated upon by a competent rhinologist, without modifying to any extent her asthma. When she first came under observation she showed the effects of incessant coughing and lack of sleep. She would wake about two or three o'clock every morning with a severe coughing spell, accompanied by dyspnea. This would last from three to four hours. Her general nutrition and digestion were poor. Her asthmatic attacks were worse during her menstrual periods. She was very nervous. The physical signs in her chest were those of bronchial asthma. The writer in the management of this case after a careful examination had three problems before him: First, the condition of the digestive organs, which in this case seemed the most probable exciting cause; second, the general underlying neurotic taint, which was very manifest; and, third, the bronchial element. The first two problems were met by the careful regulation of the mode of life, diet, etc., and the use of such drugs as would improve her digestion and tone up her nervous system. The third problem was met by intratracheal injections. These injections gave prompt relief, so that in less than a week she could sleep at night without inconvenience. The permanence of the benefit was undoubtedly influenced by the general treatment, yet the marked relief which followed the injections, when other methods had failed, was convincing proof of their efficacy.

Let us consider now some of the details to be observed in the use of this method. The writer has used the Muir tracheal syringe in his work. This syringe has a glass barrel holding four drams, with a cannula suitably bent for tracheal injections. A strong light, such as is commonly used in throat examinations, is advisable, although not absolutely essential. A laryngoscopic mirror is used to guide the cannula into the larynx. The technic is similar to laryngeal applications. A little practice and the observation of a few special rules will enable one quickly and easily to introduce the injection into the trachea with the minimum amount of discomfiture to the patient. The patient should hold his tongue out and the operator should introduce the cannula of the syringe guided by the mirror, during a deep inspiration. If the patient inhales gradually, slowly and steadily, the cannula can be introduced between the vocal cords, and from one to two drams injected without inconvenience. The operator should introduce the fluid gradually and steadily, not in spurts, and the whole amount must be introduced before the end of inspiration, otherwise choking will take place. The technic is comparatively simple in most cases, but in a few instances much dexterity will be required. The operator should explain to the patient just what is required on his part, and he can confidently assure the patient that the introduction will not cause pain. The choking sensation can be largely controlled voluntarily if the patient will steadily inhale during the injection. This may be difficult the first few times, but the knack can usually be acquired without trouble. The success of the method depends upon the co-operation of the patient and a reasonable degree of skill on the part of the operator. Unless one has the intelligent co-operation of the patient it is useless to attempt treatment by this method. This treatment is no more disagreeable than other applications to the throat and larynx.

The only cases where the writer has failed in the use of this method were dispensary patients where it was impossible to make them understand what it was necessary for them to do. After the cannula is in the trachea it is not necessary to keep the mirror in the throat while making the injection. If the curve of the instrument is not right, or if the operator is not careful, the injection may be made into the esophagus instead of in the trachea. One can easily tell

when the fluid is in the trachea by the coughing. The patient's sensations are also a guide. The injection runs into the ramifications of the bronchi and can be felt for a considerable length of time. Sometimes the patient feels the injection more on one side than on the other. This can be regulated to a certain extent by the patient inclining the body to one side. It also depends upon the inclination of the cannula in the trachea. The injection is usually felt more on the affected side, due presumably to greater sensitiveness of the mucous membrane of the bronchi on that side.

There are certain conditions that make the procedure difficult. Peculiarities in the shape of the epiglottis render the introduction of the cannula difficult. The epiglottis in one case under treatment is curved laterally and bent backward so that the cannula has to be introduced through a narrow slit.

Where the throat is sensitive, as in tuberculous laryngitis, it is advisable to spray the parts with a four-per-cent. solution of cocaine before using the injections. Nervous patients, especially those with sensitive throats, offer some difficulties, but these can be overcome in nearly every instance if patience and skill be used. Early in the writer's experience, he was in the habit of using a cocaine spray before the first injection, but this practice has been found unnecessary in the large majority of instances. When the larynx is placed high and the epiglottis upright, the cannula can be introduced easily without the mirror by simply pressing down the base of the tongue.

The selection of drugs and more especially the proper choice of a vehicle are very important. The writer's experience has been limited almost entirely to pure olive oil as a vehicle. This is non-irritating, easily absorbed, facilitates expectoration of the mucus and adds nutrition to the body in proportion to the amount used. In choosing drugs to be dissolved in the oil, preference has been given to those having antiseptic or sedative action. The list of drugs that have been used is a long one. The writer will confine himself to those which he has used. Creosote, 1 to 2 per cent., was used in the first few cases, but has been replaced by a solution containing menthol, 2 to 4 per cent., and liquid guaiacol, 1 to 2 per cent. Camphor is frequently added in the same proportion as the menthol. The writer has used ichthyol, 2 per cent., also iodoform, 2 per cent. A limited experience with chloretone, 2 to 4 per cent., combined with camphor-menthol, shows it to be of service. After the solution has been prepared, filter it through cotton or fine cheese-cloth to remove any sediment, then sterilize by placing the bottle in a water-bath and boiling the water for at least forty minutes. Of the various solutions mentioned above the menthol-guaiacol has been used more than any other.

The writer from his own personal experience with this method feels justified in drawing the following conclusions:

1. It is of no advantage in acute bronchitis, at least during the congestive stage.
2. It is of distinct advantage in subacute and chronic bronchitis.
3. It is of positive benefit in bronchiectasis.
4. It is valuable in pulmonary tuberculosis, relieving many of the symptoms, especially those due to secondary infection.
5. It quickly relieves the distressing symptoms of asthma. The amount of relief and the permanency depend largely upon the predisposing and exciting causes.
6. It in no way interferes with other lines of treatment.
7. The writer has never seen harm follow its use, although in a very few instances it excited severe coughing for a short time.

PRESBYOPIA: ACCOMMODATION: ASTIGMATISM.

BY NORBURNE B. JENKINS, M.D.,
OF CHICAGO.

GLASSES are fitted to readers about forty years of age by rules and tables. The rules and tables in standard text-books have not been changed in fifty years and are supposedly based on tests of emmetropic or perfect eyes. Farsighted, nearsighted and astigmatic eyes made perfect by glasses may be used to make up tables, for emmetropes are hardly available, since about one person in a hundred is emmetropic.

In youth the focusing muscle can so mold the soft crystalline lens that fine print is distinct as near as three or four inches to the eye. As age advances the lens hardens and decreases the active focusing power until fine print, such as footnotes, can no longer be read at the proper reading distance. This condition is presbyopia. The active focusing power gradually decreases until about the seventieth year when the focusing muscle loses nearly all power over the hardened lens, and at this age the perfect eye needs for reading a magnifier equal in strength to what the active focusing power was just before presbyopia came on.

The statements here given are in standard text-books of ophthalmology: "Presbyopia is present in the perfect eye when fine print can no longer be read at eight and one-half inches from the eye." "After the age of forty-five perfect eyes need magnifying glasses for reading." "Some perfect eyes need magnifiers as early as the fortieth year." "After forty-five readers without magnifiers are nearsighted." "The perfect eye requires for reading an active focusing power of 4.5 D." "In presbyopia select the weakest magnifier which makes fine print distinct at eight and one-half inches from the eye. If the eye is farsighted, nearsighted or astigmatic, correct the imperfection and add the weakest magnifier which makes fine print distinct at eight and one-half inches."

Eight and one-half inches has little to do with presbyopia or prescribing glasses.[1] Those with perfect eyes who can read fine print at nine or

ten inches from the eyes are not presbyopic. If fine print can be read at nine or ten inches with glasses which correct all farsightedness, nearsightedness and astigmatism there is no presbyopia. The proper reading distance for people past middle age is *more,* often *much more,* than fourteen inches. If the eye in age sees fine print distinctly at eight and one-half inches, the glass is too strong and reading can not be held far enough from the eye.[2] The more print is magnified, the nearer it must approach the eyes, so, too, powerful magnifiers harm the aged by making too much convergence necessary and by doing all of the work of the focusing muscles.

In many presbyopes with uncorrected astigmatism, magnifiers fitted by the eight and one-half inch rule may apply, but this is not correction; it is injurious substitution by magnifying. In astigmatism, if the proper glass is not used, magnifying must make up for imperfect definition. If print is magnified, fineness and sharpness of outline are not so necessary, but the nearer must reading be held to the eyes. In old age if there is no astigmatism, or even with astigmatism perfectly corrected, a glass that makes fine print distinct at ten, eleven or more inches may do for continuous reading. If astigmatism of 1 or 2 D. is uncorrected, continuous reading is not possible unless the crystalline lens is soft enough, or unless there is enough magnifying to make fine print distinct at about eight or nine inches. If high astigmatism is uncorrected there must be for continuous reading either an active focusing power of more than 4.5 D. or its equivalent in magnifying, and this would make fine print distinct even nearer than eight and one-half inches.

Astigmatism is usually overlooked or imperfectly corrected. In uncorrected astigmatism, reading may be held so close that convergence fails and only one eye is used, the sight of the other is suppressed and in time becomes more or less amblyopic from lack of proper use.[3] The aged can not hold print close and use both eyes at the same time. Presbyopes who hold print close read with only one eye. If one eye is out or if the sight of one eye is suppressed the aged can read with nearly any magnifiers.

Most presbyopes with proper glasses can read nearly or quite as much as they ever could. If there is no astigmatism and the eyes are exactly alike, the presbyope often selects proper glasses for himself, is easily fitted, but not by the eight and one-half inch rule in the text-books.

Until the fiftieth year most people with farsighted, nearsighted and astigmatic eyes can read fine print, with glasses which totally correct these imperfections. Many at fifty-five years of age and some at sixty years can do this. Many, with normal distant vision, at fifty to sixty years of age have never used reading glasses, and yet are a trifle farsighted or astigmatic.

Presbyopia does not come at the fortieth year. Those who need glasses this early have farsightedness, nearsightedness or astigmatism. Belladonna is not used in testing the eyes of the aged, so the focusing muscle may mask imperfections after the fortieth year almost as much as earlier. Latent imperfections may exist until the sixty-fifth year.

Presbyopes who read several hours daily can not be fitted by rules in text-books. Aged readers do not need as much active focusing power as 4.5 D. About the seventieth year the nearsighted of 3 D., 13 inches, need no reading glasses; the farsighted of 3 D. need magnifiers of about 6 D., while the perfect eye needs a 3 D., 13 inch magnifier. The glass required and the distance at which fine print can be read depend upon the habitual reading distance, the kind of imperfection and upon the active focusing power.

Rules and tables can not be followed in fitting glasses. The table here given may aid in fitting the eyes of readers. Total farsightedness, nearsightedness and astigmatism are first corrected and the magnifier given in the tables added.

Age.	50	55	60	65	70	75
D.	0. to .75	.0 to 1.5	.75 to 2.	1.5 to 3.	2.to 3.5	2.5 to 4.

The following is a near-point table showing the distance at which fine print can be read at different ages. It is based on imperfect eyes, but glasses were used which corrected the total farsightedness, nearsightedness and astigmatism, but not presbyopia. The table is only approximate for the near point varies a little in different persons of any given age, even in eyes of any given imperfection. The active focusing power is somewhat greater in astigmatic, in farsighted and even in many nearsighted eyes,[5] than in perfect ones. The near point is given in inches and centimeters and the active focusing power in diopters.

Age.	10	15	20	25	30	35	40	45	50	55	60	65	70
In.	2 2-5	2 4-5	3 1-5	3 3-5	4 2-5	5 1-5	6 2-5	7 3-5	9 1-5	12	(20)	(50)	(100)
Cm.	6	7	8	9	11	13	16	19	23	30	(50)	(125)	(250)
D.	16	14	12	11	9	8	6	5	4	3	2	1	.5

In youth the active focusing power (amplitude of accommodation) depends almost entirely upon change of shape and but little upon change of position of the soft crystalline lens. In age the hard lens changes much in position and but little in shape and yet there may be considerable range of focus. Change of the size of the pupil and of the opening between the eyelids may directly contribute to the active focusing power. Pupillary contraction is probably a greater aid in reading than forward movement of the lens. The power of the pupil is best studied in lensless eyes. Cocaine or atropine is instilled until complete dilatation. A given magnifier now makes fine print distinct at a certain distance. If eserine is afterward used the pupil contracts to its utmost and the print will be distinct at a nearer distance with the same magnifier. In perfect eyes, or eyes made perfect by glasses, the activity and size of the pupil change but little with advancing years.[6] Is the small pupil of adults

and the aged normal? It may indicate eye strain, for it is not present in perfect eyes.

MEDICAL PROGRESS.

Agglutination of Pseudodiphtheria Bacilli by Antidiphtheritic Serum.—Scientific investigations have recently tended to confirm the opinion that the so-called pseudodiphtheria bacillus and the Klebs-Loeffler organisms are closely related species and that possibly under certain conditions they may be transferable forms. This has been gathered from many similarities in their characteristics. The subject is of vital importance in its relation to the bacteriological diagnosis of diphtheria. CH. LESIEUR (*Comptes Soc. de Biologie,* Aug., 1901) reports the study of seventy varieties of diphtheria and pseudodiphtheria bacilli from the standpoint of agglutination by antidiphtheritic serum. His work shows that this property is an inconstant characteristic of the true Klebs-Loeffler bacillus and is in no way related to its virulence. Furthermore that certain varieties of this organism can be agglutinated by the serum of horses immunized by cultures, while they do not react to the serum of horses immunized by toxins. The pseudobacillus conducts itself toward these sera precisely as does the true organism and by this means cannot be differentiated from it. This fact constitutes a new presumption in favor of the identity of certain species of pseudodiphtheria bacilli and the true diphtheria organism.

Navel Infection of the Newborn.—This subject is of interest on account of its somewhat frequent occurrence and the varied bacteriological conditions which underlie it. M. WASSERMANN (*Virchow's Archiv,* B. 165, H. 2) reports the study of eleven cases occurring in the Charity Clinic at München. All of the cases were fatal. On autopsy all showed the umbilical arteries full of thrombi and pus throughout their entire extent. In seven there was present a pneumonia with hemorrhagic fibrinous exudation accompanied by necrosis and abscess formation. Four were submitted to bacteriological examination. In all of these cover-slip preparations of the pus and sections of the lungs showed a bacillus whose morphological appearances were identical with those of the bacillus pyocyaneus. Its cultural and staining characteristics also corresponded with those of that organism. It was pathogenic for rabbits on inoculation and at death was found in their heart's blood. It is evident that this organism was the producer of the navel infection. This work increases the evidence in favor of the opinion that under certain conditions the bacillus pyocyaneus is a pathogenic organism for man.

Lecithine and Elimination of Uric Acid.—The action of lecithine upon the phenomena of nutrition has recently excited much interest by reason of the favorable results following its use in several of the so-called wasting diseases. It has been supposed that the elimination of uric acid is diminished by its use. This is an important question, as it concerns the destruction of the nucleins. The most recent study along this line comes from ALY ZAKY (*Comptes Soc. de Biologie,* Aug., 1901) who investigates the subject experimentally on two men and one woman. These were placed upon a stipulated diet and each was given thirty centigrams of lecithine daily. The estimations of the amount of uric acid excreted were obtained by the method of Tolin. There was an increase in the total amount of nitrogen excreted with a diminution of phosphoric acid. The amount of uric acid was, as a rule, decreased. All showed an increase in weight inside of ten days.

Bacteriology of Abscess Pus.—The bacteriological study of abscess pus is always of interest as conducive to the knowledge of the diversified microbic conditions which underlie circumscribed inflammation. W. SILBERSCHMIDT (*Ctlblt. f. Bak.,* Aug. 8, 1901) reports an interesting find in a man, fifty-eight years of age, who developed an abscess of the thigh. On operation the pus was found to be of a dark-brown color and very foul. Death followed in seven days. On bacteriological examination four organisms were found in the pus, as follows, a few cocci, a fair number of spindle-shaped bacilli, many long threads and many sharply curved spirilli. The last three organisms were also found in the lungs. Inoculation of the pus into guinea-pigs and mice produced abscesses from which the last three organisms were recovered. All of these organisms could be cultivated on the ordinary media, glucose-agar, agar, bouillon and gelatin, but the last three refused to grow after several transmissions. He believes that the process is to be regarded as a mixed infection due to the presence of the spindle-shaped bacilli, threads and spirilli.

Lecithine in Tuberculosis.—The favorable influence of this substance when administered to tuberculous patients has been announced in many quarters as the result of clinical observation. H. CLAUDE and ALY ZAKY (*Comptes Soc. de Biologie,* Aug., 1901) have recently studied the subject from both experimental and clinical standpoints. They subjected guinea-pigs to inoculations with tuberculous sputum and pure cultures of the bacillus. To some of these lecithine was administered in an oily emulsion containing 5 centigrams to the cubic centimeter. Others were preserved as control animals. These lost greatly in weight as the result of the tuberculous infection; some of them whose weight was 670 grams at the beginning were reduced to 490

grams at death. Those which received the lecithine suffered a much less reduction of weight and some even showed an increase. In a series of these animals which weighed collectively 1680 grams at the beginning this was increased to 1800 grams at death. It could not be said, however, that by this treatment the duration of the infection was materially prolonged. They observed clinically two cases of pulmonary tuberculosis in which the diagnosis had been established by microscopical examination of the sputum. To each of these was administered daily six pills of five centigrams each. Both increased in weight, one showing a 900-gram increase in six days. They do not think that lecithine has any specific effect upon tuberculous infection, but that it happily modifies the nutrition, making it more active, and diminishing the excretion of phosphorus. They thus consider it a valuable adjunct in the treatment of tuberculosis.

Negative Chemiotaxis of Leucocytes.—This phenomenon was first described by Metchnikoff in 1884, who, in examining the organs of rabbits and guinea-pigs very susceptible to anthrax and dead of this affection, remarked that phagocytosis was not observed here in spite of the fact that the leucocytes maintained their ameboid movements and hence were not poisoned. Since then it has been observed many times that a negative chemiotaxis of the leucocytes took place in animals very susceptible to a given organism when infected with it. A. ZILBERBERG and J. ZELIONY (*Annales de L'Institut Pasteur,* Aug. 25, 1901) have studied this question with respect to the infection of rabbits with the organism of fowl cholera to which they are especially susceptible. They injected into the auricular vein of three rabbits 4 c.c of an emulsion of 20-hour virulent agar cultures of this organism. Each rabbit received the contents of three or four such cultures. They were then killed at intervals of four, six and eight minutes after inoculation and microscopical study was instituted. They also submitted rabbits to subcutaneous and intraperitoneal inoculation with this organism and made similar study. In order to ascertain if there was a poisoning of the leucocytes, they injected these organisms into the peritoneal cavity of rabbits in which an artificial leucocytosis had been previously produced; no phagocytosis being instituted they then injected non-virulent staphylococci cultures. In every case the leucocytes evinced a phagocytotic action against these staphylococci. These phagocytosis often observed after the inoculation of supposedly virulent cultures of this organism is due to the presence in the same of non-virulent as well as virulent bacilli. The absence of this phagocytosis is not due to a poisoning of the leucocytes, but to a true negative chemiotaxis. The leucocytes preserve this property until the death of the animal and are even able to distinguish between virulent and non-virulent organisms in artificial cultures.

Tubercle Bacilli in the Stools of Tuberculous Persons.—It is the general impression that, except in cases of intestinal tuberculosis, the demonstration of the specific organism in the stools of tuberculous persons is attended with the greatest difficulty. D. ANGLADE (*Comptes Soc. de Biologie,* Aug., 1901) reports the investigation of a series of tuberculous cases from this standpoint. He claims to have had no difficulty in demonstrating the presence of the specific bacilli in the stools of such, even when there were no indications of intestinal tuberculosis present. His method of examination is that employed in the ordinary microscopical study of this organism by staining with Ziehl's solution and decolorizing with hydrochloric acid. He thinks that the intestine is a favorite route for the elimination of the bacillus and that the fecal matter is more often a source of dissemination of this organism than is generally supposed. He advocates the proper disinfection of the stools in all cases of tuberculosis.

Nephrectomy and Spermatogenesis.—The influence of nephrectomy on the genital function has hitherto received little or no consideration. The importance of the subject from a practical standpoint has led GUSTAVE LOISEL (*Comptes Soc. de Biologie,* Aug., 1901) to experimental work along this line. He removed the left kidney from a dog and thirty-five days after the operation made histological examination of the testicles. He found the intercanalicular spaces filled with spherical granulations which stained an intense black and were soluble in chloroform. These were found almost exclusively in the protoplasm of the interstitial cells. In the same region a certain number of the blood-vessels showed chronic inflammation. These granulations were found in the interior of the seminiferous canaliculi in the following distribution: (1) Very numerous in the zone of epithelial transformation (spermatozoids); (2) less abundant in the spermatocyte zone; (3) only a very small number in the zone of multiplication (spermatogenesis). The spermatozoa seemed to be normal in the greater part. He believes that these changes signify the degeneration of certain cells and alteration of the internal secretion of the testicle. These observations are new and increased work should be done along these lines.

Dilatation of Narrow Esophageal Strictures.—According to the statements of A. HENLE (*Centralblt. f. Chir.,* No. 34, 1901) many esophageal strictures which permitted only the passage of small quantities of fluid have been rendered permeable by the method of Socin. This consists in letting the patient wash down with his fluid food a small leaden shot to which is attached a fine, high-grade silk thread. Through the gastrostomy wound this is fished or washed out and then larger and larger threads are pulled through followed by instruments. Finally the gullet is made passable to solids. The objection to this highly rational procedure is that the thread and

sinker can not be reached in the stomach. Henle proposes and has used with greatest success a thread with several small iron sinkers, placed about an inch or two apart. The "fishing" for these is done rapidly, surely, and safely with a sound like a urethral sound converted into a strong magnet by an electric coil about its handle. The patient feels the thread jerk when the sinkers are attracted, and often the contact click can be heard by the surgeon. The sound-magnet, of course, is introduced through the gastrostomy fistula. The apparatus is not expensive.

Inunction versus Injection in Syphilis.—Sixty-nine cases of syphilis, which have been under his care for more than a year continuously, and of which 37 received intramuscular injections and 32 inunctions of mercury, are reported by C. F. MARSHALL (*Lancet*, Aug. 24, 1901). Of those subjected to injections 16 had relapses and 4 had iritis; of the inunction cases 7 relapsed and only 1 showed iritis. The conclusion drawn is that, although the injections have the advantage of cleanliness and privacy, for some reason they are deficient in certainty and ultimate medicinal influence, perhaps through imperfect absorption.

Pathogenesis of Flat Foot.—The much-vexed question of the pathogenesis of flat foot is epitomized by DE VLACCOS (*Revue de Chirurgie*, No. 8, 1901) in the following terms: The diversity of synonyms also indicates the divergence of the theories as to its cause. Those commonly employed in France are tarsalgia, pes planus et dolorosus, and functional impotence of the peroneus longus, and are founded upon the theories respectively of arthritis (Gosselin), laxity of the tarsal ligaments (J. Guérin), relaxation of the dorsal ligaments (Le Fort), of the plantar ligaments (Tillaux), without any direct evidence of truth. All the lesions enumerated by the above hypotheses do certainly exist, but rather as secondary than as primary to the flat-foot. The real causal factors appear to be these. Vertical saw-cut through the sagittal median axis of the leg does not cut the middle of the os calcis, but rather between it and the internal border and often passes through or internal to that border itself in the normal subject. Hence the normal point of support in the foot at the os calcis is eccentric. Similarly the same plane of the saw-cut passes internal to the center of the astragalus, and only very rarely through its center. It is therefore easy to conceive why in some cases with this eccentric arrangement a twisting occurs so that at first a weakening, then a flattening of the plantar arch and finally an outward rotation occurs. At first the strong muscle tendons from the calf and in the sole of the foot with the ligaments resist, but finally something happens to break down the equilibrium. The os calcis is forced to rotate outward on its anteroposterior horizontal diameter, soon followed by the astragalus which then begins to strain at great advantage the calcaneo-scaphoid and the astragalo-scaphoid ligaments and joints. Faulty foot-gear undoubtedly is important, but must be regarded as rather secondary to anatomical error as delineated above. Perhaps its most direct action in accentuating the result of this faulty anatomy is that the external malleolus is pushed inward by contact with the shoe and therefore increases the rotation of the astragalus and os calcis.

Typhoid-Fever Bed-Bath Apparatus.—The Brand method of treating cases of typhoid fever, or at least the cold bath of some sort, is almost universally used now, but there is considerable difference of opinion in regard to the relative efficacy of slush or sponge baths as compared with the tub. The extra work necessitated by the tub-bath, together with the severe exertion on the part of the patient, has raised considerable doubt in the minds of many whether the tub really is of sufficient value to continue its use instead of sponge-bathing, especially since the tub is practically impossible in private practice. To avoid many of the disadvantages of the tub R. BELLAMY (*N. Y. Med. Jour.*, Sept. 7, 1901) has invented a special tub so arranged that a small wire mattress bed, on which the patient can be easily rolled, fits into the top of the tub and can be lowered into the water by means of small chains attached at each corner and regulated easily by a crank. Two nurses can thus give a tub-bath without any difficulty and also avoid any undue movement or exertion on the part of the patient. This would doubtless be very valuable in hospitals and could perhaps be employed at times in private practice.

Function of the Tonsils.—There has been such a wholesale removal of tonsils during the last few years that a reaction has now been started by some who believe in a more conservative treatment of the organ. Although we have found no function of the organ essential to the body welfare, no doubt its presence signifies that it is not without use. R. C. MATHENY (*Med. Rec.*, Sept. 14, 1901) believes that this lymphoid tissue which, together with the pharyngeal and lingual tonsils, forms a complete circle around the pharyngeal orifice and acts as a barrier to the passage of much that is deleterious to the organism. The presence of so much lymphoid tissue, the principal function of which is absorption, naturally leads one to believe that Nature has thus made an heroic effort to guard an important gateway. The fact that they are frequently inflamed may not indicate that they should be removed, but rather that they have received the toxic substance which might have caused greater havoc if allowed to enter the system elsewhere. He, however, does not argue so much against removal of the tonsils, for there are, of course, many which are very nefarious possessions, but rather he insists that the condition should be carefully observed and simple hypertrophy should not be considered an indication for operation.

Cause of Malignant Tumors.—Another parasite is now described as being the cause of

cancer and whether it may be later identified as the same organism that has been previously discovered by other persons is not known. J. E. BLAKE (*N. Y. Med. Jour.*, Sept. 14, 1901), in reviewing the work of Max Schüller on this question, says that he has positively found a parasite present in both sarcomata and carcinomata which has been isolated and when injected into the peritoneal cavities of guinea-pigs causes a similar growth. The secondary growths contain the parasite and it has again been isolated from them. The infectious character of malignant tumors would thus seem to be proven, but no one has yet found the organism outside the body.

Laryngeal Tuberculosis.—Laryngeal tuberculosis is one of the most painful and distressing diseases the physician sees and it is doubly unsatisfactory for the treatment seems almost useless, so far as local applications are concerned. ST. C. THOMSON (*Phila. Med. Jour.*, Sept. 14, 1901) says that the only two local methods of treatment which deserve any attention are the lactic acid and surgical procedures. The former is nothing more than a superficial caustic which could not in any way affect deep ulcerations or a perichonditis, except perhaps by increasing the irritation. Freudenthal, who has used it freely, states that "it ought to be dispensed with as antiquated and barbarous torture of the patients." So far as curettage is concerned many surgeons have employed this method in numerous cases without being able to report a single cure and eminent authorities have said that "the permanent radical cure of the local lesion of tuberculous laryngitis is not materially hastened by the various methods of treatment in any but an insignificant number of cases." The most satisfactory means of treating local lesions in the larynx are the same as when the lesion is located in any other part of the body and consist of attention to the general health and systemic improvement with local symptomatic sprays, etc. The specific cure for this disease has not yet been found, and until it has, the most rational means of improving the patient are found in assisting and fortifying Nature against its inroads.

Treatment of Whooping-Cough.—So little progress has been made in the treatment of whooping-cough that suggestions are gladly received and tried. T. J. MAYS (*N. Y. Med. Jour.*, Sept. 7, 1901) believes that this disease, as well as many pulmonary affections, is the result of irritation of the pneumogastric nerve and that the most successful mode of treatment is that which is applied locally to this nerve. Accordingly, counterirritation is used along the side of the neck immediately over the course of this nerve from the jaw to the clavicle. Gentle massage and kneading every two or three hours sometimes yield good results. A mustard plaster, two inches wide, reapplied till the full effects of the mustard are present is usually very efficacious. A combination of chloral, camphor and menthol may be used and in severe and obstinate cases he recommends the hypodermic use of silver nitrate. First, inject five minims of a 2½-per-cent. solution of cocaine; then detach the syringe from the needle and after filling the syringe with a 2½-per-cent. solution of silver nitrate, inject three to six minims of this solution by screwing the barrel onto the needle left in place.

Toxin and Antitoxin in Tuberculosis.—In 1895 Maragliano of Genoa pointed out the possibility of separating various toxic substances from pure cultures of tubercle bacilli. It was his purpose to utilize one of these toxins for immunizing horses, and in this manner to develop a specific antitoxin. L. FRENKEL and O. BRONSTEIN (*Berl. klin. Woch.*, Aug. 19, 1901) have produced toxins after the Maragliano method and have investigated the value of so-called antitoxic horse serum. They state that the antituberculous serum is harmless to men and animals. From experiments with guinea-pigs they conclude as follows: (1) A variety of derivatives are obtainable from cultures of tubercle bacilli; the most important of these derivatives are the tuberculous toxin (fluid and precipitated); the watery tuberculin and its precipitate; tubercle bacilli divested of fat (bacilli digrassati); (2) most of these derivatives are powerful poisons producing toxic effects in proportion to dose; (3) the injection of sufficient doses causes the death of animals with characteristic phenomena; (4) by means of small, but gradually increasing doses, animals can be immunized; (5) the serum of immunized animals possesses powerful antitoxic properties, which are capable of demonstration experimentally with relation to each of the toxins mentioned.

Infant Feeding.—After reviewing the various methods of modifying cow's milk to make it acceptable to an infant's stomach, C. G. KERLEY (*Med. Rec.*, Aug. 31, 1901) gives a table in which he combines cream, whole milk and water in such proportions that any desirable percentage can be easily obtained. He believes that during the hot months all milk should be heated to at least 155° F. for twenty minutes. It is rendered more indigestible in this way, but much safer. Peptonization is not successful, for when completely done the child will not take the bitter peptones and if only partially done the change is valueless. Cereal water added to the milk causes finer curds to form, but probably does not assist much in digestion. These diluents are useful on account of the nutrition they give rather than the mechanical assistance they offer. Cow's milk contains a large quantity of proteid in the form of casein which is represented by lactalbumin in mother's milk. To get rid of this indigestible casein in cases in which feeding is difficult, rennet may be used and the simple whey which is left may be given the infant for a few days, gradually increasing the fats in the form of cream. When the food is too strong, the appetite fails and if more is forced the child vomits. Fat in excess almost always causes colic and green, frequent

stools. Habitual colic, almost without exception, means too much proteid and it is one of the most frequent causes of habitual constipation. Sugar is most easily digested and seldom causes trouble.

Blood Examination.—The solutions in most common use for fixing the morphological elements of the blood in counting the red blood-cells with the Thoma-Zeiss apparatus are a 3-per-cent. aqueous solution of sodium chloride, Lugol's solution and Hayden's solution. The advantage of these solutions lies in the fact that they fix the corpusclar elements while they leave the blood plates unchanged. G. LA ROSA (*Centlblt. f. Path.*, July 15, 1901) has undertaken a series of investigations in order to ascertain which are the most advantageous solutions for this purpose. In addition to the above solutions he also employed the following: (1) A 1-per-cent. solution of sublimate to which .7 per cent of sodium chloride is added; (2) osmic acid solution, 1 to 4,000; (3) picric acid solution, 1 to 300; (4) tannic acid solution, 1 to 150; (5) Acquisto's solution; (6) Dotto's solution. He employed normal blood and also that of anemic and chlorotic patients. The picric and tannic acid solutions are not advantageous, since they cause an impairment of the morphological elements. The sodium chloride solution is to be discarded, because it alters the shape of the red blood-cells and makes their enumeration difficult. All of the others yield good results.

The Mechanical Reduction of Body-temperature.—By repeatedly tapping or striking the chest-wall with an elastic silver instrument resembling a paper-knife in shape, ERNI (*Corr' blatt f. Schweizer Aerzte,* Sept. 1, 1901) claims to be able to reduce the temperature of fever-ridden phthisical patients to an extent varying from 0.2 to 0.5°C. The instrument is held lightly between thumb and forefinger, and the entire chest-wall repeatedly struck, avoiding only the mammæ and bones lying directly beneath the skin, as the clavicle and sternum. The tapping is repeated every two days, each sitting being preceded by rubbing in a salve, such as a 15-per-cent. salicylic-turpentine preparation, to soften the skin. After being tapped for ten or fifteen minutes, the skin becomes very red; a dull ache is at first experienced by the patient, but this is rapidly succeeded by a feeling of comfort and well-being. The treatment is not advisable in women during menstruation, and is to be avoided in nervous individuals generally on account of the excitement it produces. The reduction of temperature by this method is explained as a purely physiological phenomenon, capable of demonstration in normal individuals.

Nasal Therapy in Neuroses.—Ten years ago, while observing a case of whooping-cough, it was noticed by L. KURT (*Wiener klin. Rundschau,* Sept. 1, 1901) that spasm of the glottis could be controlled by irritation of the conjunctiva or of the nasal mucous membrane. Since that time Kürt has employed stimulation of the nasal mucous membrane in the treatment of various neuroses of a spastic nature. The stimulation may be produced by various mechanical processes; for more persistent and powerful irritation quinine or pulverized sugar are used, or powdered rhizome of veratrum album. Among the conditions successfully treated by this means are laryngeal spasm, blepharospasm, *tic convulsif.* In rare instances epileptic attacks are said to have been controlled by strong irritation of trifacial branches. In asthmatics and in persons suffering from nervous cough the method does not succeed.

Treatment of Cancer by X-Rays.—The treatment of external forms of cancer by X-rays is reported to have caused healing or improvement in a series of cases persistently treated by F. H. WILLIAMS (*Boston Med. & Surg. Jour.*, Sept. 12, 1901). The exposure of the diseased area to the X-rays for a few minutes two or three times a week for several weeks, is in general what is required. Where the growth is extensive, a longer time is necessary; on the other hand in early cases ten exposures or even less may suffice. The cases treated by Dr. Williams include not only the smaller and lesser forms, but some which were inoperable. Diagnosis in all these cases was based upon careful microscopical examination. Some of the growths were typical epitheliomas; others were of the rodent ulcer type; others were clinically epithelioma, but microscopically were composed of chronic inflammatory tissue.

A Peculiar Characteristic of Malarial Blood.—If two drops of blood from different malarial patients be placed in contact under the microscope, it is noticed that after a minute or so the red blood-cells arrange themselves in groups and masses, each group consisting of from 5 to 100 erythrocytes. The leucocytes do not participate in the group-formation. The rouleaux of normal blood do not form under these conditions. This peculiar agglutination-power is acquired by normal blood by contact with malarial blood. As long as this phenomenon persists, malaria cannot be regarded as cured, according to the statement of GRIXONI (*Gazz. degli osped.*, No. 57, 1901). The agglutination reaction is destroyed by the action of quinine. Its continued presence is said to be of importance from the standpoints of diagnosis, prophylaxis and prognosis.

Cystitis, Pyelitis, and Pyelonephritis.—In a very complete article upon the diagnosis and treatment of the above conditions, T. R. BROWN (*Med. Rec.*, Sept. 7, 1901) gives many valuable hints. The great majority of such cases are due to infection with various micro-organisms (of which the colon bacillus is the commonest) which may reach the bladder exogenously or endogenously. Simple urinary hyperacidity may so closely simulate vesical infections that only careful microsopical and chemical analysis can determine the nature of the trouble. Prophylaxis is most essential, especially in all cases needing catheterization. While an absolute diagnosis of

renal infection can be made only by ureteral catheterism, a probable diagnosis can usually be made after a determination of the relation of albuminuria to pyuria is made and by a careful examination of the bladder around the ureteral openings. Speaking generally, in all cases of bladder infection, even where pyuria is of high grade, the albumin is slight, while in pyelitis and pyelonephritis there is much more albumin present. This point is especially important where ureteral catheterism is impossible. Contrary to most opinions a great majority of both bladder and renal infections are associated with acidity of the urine, that is, due to germs which do not break up urea. In nearly all cases of renal infection causing alkaline urine, after a time a stone is formed about the bacteria as a nucleus.

Tuberculosis and Disinfection.—Much diversity of opinion exists as to the value of various methods of disinfection when applied under different conditions to the bacillus tuberculosis. Practically the entire renovation of infected apartments has been deemed necessary for effective results. Recently FRANK STEINITZ (*Ztschrift f. Hygiene u. Inf.*, Aug. 27, 1901) has gone over the entire subject from an experimental standpoint. His researches were carried on by submitting tuberculous material to the action of various disinfectants and subsequent inoculation into guinea-pigs. Due precautions were taken in order that none of the antiseptic should be carried into the bodies of the research animals and thus lead to false conclusions. He experimented with fresh sputum, contaminated clothing and infected apartments. The disinfecting agents employed were iodine trichloride, formalin and formaldehyde, sulphate of copper, hydrochloric acid, alcohol and sublimate and sublimate alcohol. Fresh sputum should be received into receptacles which can be burned or disinfected by heat, or such sputum should be exposed to the action of a 1-1,000 sublimate solution for five hours. Those portions of dwellings which have been especially contaminated should be thoroughly washed with a 1-500 sublimate solution and all washable clothing should be soaked in such a solution for three hours. The entire dwelling should then be submitted to the action of formaldehyde gas.

Hereditary Syphilis and Tuberculosis.—The ultimate prognosis of this form of syphilis is discussed by KARCHER (*Correspondenz-Blatt für Schweizer Aerzte*, Aug. 5th, 1901). He believes with Hochsinger and Pott that the chances of eradicating all traces of it from the system by early and appropriate treatment are much better than is generally supposed. But while the majority of children with inherited syphilis, who have had even one thorough course of mercurial inunctions, show no further signs of this malady, their susceptibility to tuberculosis in its various forms is much greater, apparently, than that of non-luetic children. Of thirty cases treated and discharged as healthy from the Children's Hospital at Basel, between 1876-1896, Karcher was able to hear of but sixteen. Of these six had died in infancy, five were found to be suffering from tuberculous affections, and the remainder were considered perfectly healthy. Karcher urges that mercurial treatment be instituted in all cases as soon as possible and be diligently carried out, not alone for suppressing present hereditary syphilis, but as a guarantee against future manifestations, as well.

Tuberculous Bacilli in Butter.—This subject was first brought before the profession in 1899 by researches carried on in the Hygienic Institute at Breslau. Since that time a vast amount of investigation has been carried on along this line and many workers have announced the frequent occurrence of so-called tuberculosis-like bacilli in butter. These organisms have practically the same staining reaction and morphology as the tubercle bacillus, but are non-pathogenic for research animals. Very recently F. KERR and M. BENINDE (*Ztschrift f. Hygiene u. Inf.*, Aug. 27, 1901) have submitted this subject to extensive examination. They conducted their investigations by fluidifying various specimens of butter and the subsequent inoculation of such material into guinea-pigs and rabbits. The former were inoculated intraperitoneally and the latter into the anterior chamber of the eye. After various intervals these animals were submitted to bacteriological and pathological examination. Forty-five specimens of butter were thus investigated in two series of studies. In the first series 11.1 per cent. and in the second 15.5 per cent. showed the presence of true tubercle bacilli. In 15 cases so-called tubercle bacilli were found. A contaminated butter-source can continuously produce infected butter or such may be only temporary. In all butter examinations for the presence of this organism, Obermuller's method is to be earnestly commended. In this work microscopical examination cannot be relied upon to differentiate true tuberculous organisms from the tuberculosis-like bacilli. In infected milk the true organism may be present in the skim milk, buttermilk, cream or butter made therefrom, but the latter two are liable to the greatest contamination. The manipulations through which the milk is passed in the manufacture of butter have no influence in separating the bacilli from the milk.

Pasteurization of Cream and Tuberculous Butter.—Diversity of opinion exists as to the efficiency of the pasteurization of cream in the prevention of the spread of tuberculosis by butter; also as to whether this process alters the nutritive value and taste of the butter. F. HERR (*Ztschrift f. Hygiene u. Inf.*, Aug. 27, 1901) studies this subject by the observation of the effect of different temperatures and various time exposures to such upon infected butter. This was also submitted to chemical examination in order to ascertain the change, if any, in nutritive value. He recommends that cream be exposed to pasteurization at 85° C. for two minutes. This is amply sufficient for the destruction of any tubercle bacilli present and has no effect upon the nutritive value or taste of the butter.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

TRAITORS IN THE RANKS.

IMMEDIATELY following the death and autopsy of the late President, there appeared signed articles in the daily press from several prominent physicians in this city, and an editorial in a leading medical journal, openly criticizing the physicians who attended President McKinley in a manner that has stung the whole medical fraternity into expressions of shame and scorn—shame that the editor of a journal that has always upheld the honor and dignity of the profession should have stooped from his high position to traduce by innuendo and covert criticism the medical men who attended the late President; scorn that any physician should have sunk to the level of the scandal mongers of the sensational press and deliberately suggest to an excited and believing public weapons of suspicion to be used at random against the men who have handled this famous case.

It can readily be imagined that it must have been trying to the yellow journals that the X-ray apparatus was not used, and that they were defrauded of a skiagram of the dying President; but that any physician should sneer at the conscientious conclusions reached by the anxious surgeons to dispense with the X-rays and should state concerning this opinion that "it seemed safer to guess than to be sure" is, we feel, little short of an insult. "What excuse," is asked, "must be offered to the public for the utter inability to find the bullet even in the dead body?" But why, we ask, should the sympathetic, overwrought public think of demanding excuses from the medical men who by their strenuous efforts prolonged, for a week, the life of the doomed President, unless the idea had been suggested? To hint to the public that they are aggrieved and that they have a right to ask the surgeons to explain "why they allowed a lost ball to be buried with the victim's body" is little short of trying to make the Nation's tragedy a popular spectacle.

It is not, however, this gallery play that deserves the severest condemnation. It is the subtle way in which many of these articles have been worded so that while they seem to mingle praise for the surgeons with lamentations over the inevitable, they nevertheless convey to the reader a startled sense of suspicion and alarm that all was not done that might have been done. We are ashamed of this utter violation of professional standards, of the manifest unfairness of making charges when the accusers could not possibly be in possession of the full details of the case, of the lack of charity in dealing treacherous, underhand blows to the few and of this holding up to public criticism a vicious cartoon of medical men so prominent that the entire medical profession must bear the scoffs. It is these things that have amazed, pained and angered the American medical brotherhood.

To so cruelly and maliciously hint that a "fatal blunder in diagnosis had been made," especially after the autopsy had demonstrated the necessarily fatal character of the wound, is evidence of a very low standard of professional ethics, and it is not to be wondered that the attending surgeons and the medical profession of the country should feel the affront and demand an apology.

THE INTESTINE AND ITS BACTERIA.

ALTHOUGH scientific investigation has accomplished much toward the elucidation of the many unsolved problems which are connected with different physiological and pathological processes from time to time inaugurated in the human body, the full significance of the intestinal bacteria to such processes has not been as yet fully appreciated. This is, without doubt, very largely

due to the great variation in the chemical composition of the intestinal contents which places before us a vast number of different nutrient conditions very few of which we are able to reproduce artificially.

The intestinal secretion acts as an adjuvant to the pancreatic and albuminoid ferments and has a bactericidal action upon micro-organisms. By its alkaline reaction it tends to neutralize the acidity produced by the digestion of the carbohydrates and the action of bacteria. The intestinal contents include all the nutritive principles necessary to bacterial life and being of the proper reaction they contain an enormous number of micro-organisms. These may be classified as obligate and facultative intestinal bacteria, different portions of the intestinal tract possessing their own peculiar obligate microbes.

Investigation has shown that the vast majority of foreign bacteria which are introduced into the intestinal tract in health perish and cannot be regained from the feces, thus proving that the body in this location is provided with means of protection from infective invasion. Research has also shown that in diseased conditions of the intestinal mucous membrane this protective power is very seriously impaired, so that foreign organisms introduced at such a time are recovered from the feces with comparative ease. The reason that the obligate intestinal bacteria are not also destroyed by these means is to be ascribed to acclimation of these organisms to the environment in which they live. The meconium is sterile, and all bacteria are originally introduced into the intestine from without, yet it has been impossible to produce sterile feces, except in the first days of life, by the feeding of sterile food, because the obligate organisms already present in the intestine are capable of indefinite multiplication.

The ability of these obligate bacteria, especially the colon bacillus, to assume pathogenic properties has in recent years been much discussed. There seems to be no doubt that when this organism wanders from its normal habitat and invades other regions of the body it may produce diseased conditions, but carefully conducted bacteriological investigations have conclusively shown that this tendency has been overestimated. As to whether this organism ever plays a pathological rôle in its normal location is somewhat doubtful, but it is probable that under conditions which materially lower the natural protective power of the intestine such may occasionally be the case.

Much that is illusory has been written and accepted in regard to the bactericidal action of many agents which are introduced into the intestine with the idea of destroying or inhibiting the growth of foreign pathogenic bacteria. Although at first sight an apparently feasible idea, careful thought will show that the employment of such means is in all probability harmful rather than beneficial, as a greater inhibiting action is exercised by these substances upon the natural protective functions of the intestine than upon the micro-organisms present. This is to be gathered by analogy from the effect of these substances when employed for a like purpose in other regions of the body. The widespread employment of intestinal antiseptics cannot be accepted at the present time as on sound foundation, as their use is based upon incomplete and faulty deductions and their employment fosters the delusion that we are employing scientific medication. Until we shall be supplied with means by the use of which we can accentuate the natural protective functions of the intestine the most logical method of ridding the tract of foreign pathogenic bacteria is that which seeks in diseased conditions to restore to the intestine its normal protective power.

THE MENOPAUSE.

In spite of what has been written on this subject in recent years, many practitioners, especially among the older men, cling to the fallacy that the change of life is a critical, that is, a dangerous time, that the profuse hemorrhages which often accompany it are in some way necessary and not to be avoided, that the whole train of gastric, nervous, and other disturbances are in some mysterious way a part of Nature's economy in passing a woman from the childbearing period to that which lies beyond it.

Consequently, those who hold such views simply follow a plan of masterly inactivity, the expectant plan it is called, leaving Nature to do the bad work and in due season provide the remedy—perhaps. It is strange that the instructive lessons which have been taught by those who pass the menopause prematurely have been apparently lost by so many. Here are thousands of women who through the loss of their essential genital organs have anticipated the change of life. They have been distributed over every portion of the civilized world, so that it would be strange, in-

deed, if some of them had not come under the eye of every observant physician. They have had no hemorrhages, at least, that is the rule, for in only ten per cent. of those from whom the ovaries have been removed do the menses persist. The nervous phenomena are common enough and in many cases the doctor is called upon to relieve such troubles. With the exception of bleeding the experience in a great many of the cases of premature menopause is not dissimilar from that which occurs at the ordinary menopause. Hemorrhage, therefore, is plainly not a necessity, and the other phenomena can often be relieved by a careful and intelligent mode of procedure.

It is not difficult to outline a plan of treatment which will apply to very many of the women who are passing through the menopause at the customary period of life, that is, between the forty-fifth and fiftieth year. The universal accompaniment of this period is the nerve shock which attends vasomotor spasm and paralysis, the flushing or pallor, and the uncomfortable sensations, nausea, vomiting, weakness, etc., which a large proportion of women experience, especially during the first year after the menses become irregular or have ceased. These phenomena are usually inevitable and it is well to recognize this fact and mitigate them as far as possible. Probably no medicament is of greater service for this condition than the bromides, especially sodium, or ammonium, or strontium, given at regular intervals, twice or three times daily, in five-, ten-, or fifteen-grain doses as the condition may indicate. Hemorrhage during the menopause is not inevitable; if it is very common, it is an evidence of disease—usually a diseased endometrium; it is occasionally an evidence of malignant disease. Between hemorrhage at the menopause and cancer there is no such relation as cause and effect. It happens that cancer of the uterus develops in a large number of cases about the period of life when the menopause usually occurs, but the percentage of women who go through the experiences of the menopause and those of cancer of the uterus as well is very small when compared with those who do not have cancer of the uterus.

The treatment for the hemorrhage is mainly mechanical, thorough curettage of the diseased mucous membrane, and it is not unusual that this treatment should be repeated, perhaps several times before the end of the menopause is reached. Not infrequently the condition of the nervous system during this period is one of decided tension and this should be carefully regarded and treated, not only with sedative drugs, but with agreeable and interesting occupation, with suitable change of climate, if necessary and possible, with well-regulated diet always, and as pleasant surroundings as the conditions of the case will allow. On the whole, therefore, it is decidedly to be hoped that the old teachings concerning the menopause and its treatment may be abandoned and that the rational foundation upon which its true pathology rests may serve the purposes of the future.

ECHOES AND NEWS.

NEW YORK.

Bequest to St. Luke's Hospital.—By the will of Daniel T. Hoag, St. Luke's Hospital is to receive a legacy of $3,000.

Yellow Fever in Cuba via New York.—Eight new cases of yellow fever have developed among the crew of the British steamer "Ethelbrytha," Captain Turgoose, which arrived in New York Friday last from Jacksonville, and indirectly from New York, with three cases of the fever on board. The eleven sufferers are being treated at the yellow fever hospital and are all doing well.

New York County Medical Society Officers.—The following officers were nominated for the ensuing year: President, Dr. Frank Van Fleet; First Vice-President, Dr. Charles N. Dowd; Second Vice-President, Robert Lewis, Jr.; Treasurer, Dr. E. W. Peet; Secretary, Dr. John Van Doren Young; Assistant Secretary, Dr. E. P. Fowler; Censors, Dr. George B. Fowler, Dr. H. S. Stern, Dr. Wendell C. Phillips, Dr. Robert F. Morris, and Dr. James F. McKernon. One hundred and seventy-five delegates were elected to the State Medical Society and a committee was appointed to arrange for a reception to the State Society when it meets at the Academy of Medicine here for its semi-annual session, October 15th and 16th.

Hospital Beneficiaries.—The late Harriet Wilcox made provision in her will for the following hospital charities: New York Skin and Cancer Hospital, $20,000; Home for Consumptives, $10,000.

New York County Medical Society and the Milk Supply.—The first meeting of the fall was held Monday, September 23d. The President, George B. Fowler, M.D., in the chair.

The chief interest of the meeting was the report of the Milk Commission appointed in January, 1900, consisting of Drs. Henry Dwight Chapin, Abraham Jacobi, W. L. Carr, and Joseph E. Winters. The report was read by Dr. Chapin, the Chairman of the committee. He first spoke of what the committee had done, having made over 800 bacteriological tests, thirty visits to farms, many of them more than 200 miles from the city, and having had two conferences with milk dealers.

"From a chemical point of view," he said, "we found the milk good. Out of twenty samples which we examined all showed at least 4 per cent., and some 5 per cent., of fat, while the law requires but 3 per cent. So we devoted our attention to the bacteriological conditions of milk and the question as to its proper handling and preservation.

"It has seemed wise to establish a standard of cleanliness for a bacteria standard to which dealers must conform. The standard prescribed by the commission is that the acidity must not be higher than 3 per cent. and that the milk must not contain more than 30,000 germs or bacteria of any kind per cubic centimeter, and that butter fat must reach 3.5 per cent.

"The amount of bacteria in the milk used in the city is something alarming. Out of twenty samples examined on a winter day, November 19th, the lowest was 90,000 germs and the highest 2,280,000, while on June 29th, with the thermometer at 90 degrees, out of twenty samples examined the lowest contained 240,000 and the highest 516,000,000 per cubic centimeter. The prevalence of bacteria, to a great extent, arises from the dirt in the milk.

"There are seven conditions on which the amount of bacteria depends—the cleanliness of the barn, condition of the cow, condition of the milker, condition of the utensils, the cooling process, the transportation, and the cleaning of the milk bottles before they are returned."

Aeration, he said, is not a success to-day as used by the ordinary farmer. In good hands it might work all right, but in many cases as at present used it resulted in an increase of germs. The three things which are absolutely necessary to secure milk comparatively free from germs are strict cleanliness, rapid and sufficient cooling, and thorough icing of milk until it reaches the consumers. In the transportation of milk, ordinary freight cars should not be used, and the ends of the cars should be kept closed, thus preventing the heated air from passing through the car and breeding the germs. The railroads could be asked to cooperate and furnish refrigerating cars in which the milk could be kept constantly on ice, and after being unloaded it should be re-iced before reaching the dealers.

The Milk Commissioners, he said, agree to guarantee or certify the milk of all dealers desiring such certificates, a special label having been printed for this purpose.

PHILADELPHIA.

Pennsylvania State Medical Society.—The fifty-first annual meeting of this Society was held in Horticultural Hall September 24th, 25th, and 26th, under the presidency of Dr. T. D. Davis of Pittsburg. The scientific program was an unusually large and varied one, and the papers were of a high standard of merit. (See MEDICAL NEWS of this week.) An innovation was the special lantern demonstration given Thursday evening. The social side of the meeting was well arranged and satisfactorily carried out. It included receptions by Dr. John V. Shoemaker, Dr. James Tyson, the Philadelphia County Medical Society, the Trustees and Faculties of the Jefferson, Woman's, and Medico-Chirurgical Colleges, and the Medical Club. Wednesday afternoon the University of Pennsylvania gave a lawn party in honor of the Society and its guests. During the week a number of special clinics were held at the various medical schools and hospitals. A full report of the scientific business appears on another page.

New Site for Children's Seashore House.—New property has been obtained for the above institution at Atlantic City. The plot extends between Annapolis and Richmond avenues, Chelsea, and is a great improvement over the old location. Three buildings will be erected. The main building will be 300 by 84 feet in size and four stories high. The two other buildings will each be made up of sixteen little cottages under the same roof and will be 156 by 44 feet. The center of the property will be left vacant for a playground. The buildings will be ready for occupancy next summer.

County Medical Society.—The North Branch organized September 19th by electing Dr. A. M. Eaton chairman and Dr. R. L. Pitfield clerk. South and West branches will probably be organized in the near future.

Western Pennsylvania Medical College.—This college in Pittsburg has opened for the session with a great many changes in the faculty. The following are the more important changes in professorships: Dr. W. H. Ingram, histology, pathology, and bacteriology; Dr. M. R. Ward, diseases of nose and throat; Drs. R. W. Stewart and J. J. Buchanan, principles of surgery and clinical surgery; Dr. S. L. McCurdy, orthopedic surgery; Dr. G. N. Munro, Jr., legal medicine.

Smallpox and the Municipal Hospital.—The opposition of the citizens living near the Municipal Hospital has taken definite form in the signing of petitions and the holding of two large mass meetings Saturday evening, September 21st. During that week 38 new cases of smallpox and 4 deaths had been reported, 26 of the new cases occurring in the Twenty-eighth Ward, where the hospital is located. The hospital authorities are about to erect an annex for the purpose of isolating smallpox patients. The citizens in mass meeting have demanded three things of the city officials: (1) The removal of the smallpox sections of the Municipal Hospital to a more isolated part of the city; (2) the immediate abandonment of the projected annex; (3) energetic instead of lax methods on the

part of the officials in fighting the disease. Medical inspectors of schools have been notified by health officers to report any cases of unvaccinated children, and vigorous efforts are being made to have vaccination made general.

The Progress of Surgery as Influenced by Vivisection.—Under the above title Dr. W. W. Keen contributes an article which is published in recent issues of the Philadelphia *Record*. The writer puts before the general public the advantages which have accrued to the surgeon and his patients from animal experimentation. From his introduction we take the following statement: "Two water companies in London in 1853 experimented on 500,000 human beings, and, as a result of the cholera, one of them killed 3,476 human beings. In that same year Thiersch, in Leipzig, experimented on 56 mice. Had the lesson of these few mice been heeded the lives of these human beings might have been saved." After speaking of the importance of antisepsis and its growth from experimentation, Dr. Keen speaks in detail of the operations upon various organs of the body which have been shown feasible by first performing them upon animals. He confines himself almost wholly to those which have occurred during his professional life in order to speak of what he personally knows. He concludes as follows: "Although I myself am not a vivisectionist, yet I could not do the work I do every day and accomplish results I do were it not for just such work, of which I take advantage. I cannot believe that any unprejudiced, fair-minded reader will not agree with me that such humane purposes should be fostered and not hindered, should be encouraged and not abolished."

Dr. Miller Honored.—Dr. John S. Miller, of Denver, Colo., formerly a demonstrator of anatomy in Jefferson Medical College and surgeon to St. Joseph's Hospital, during a visit to this city was tendered a dinner by his professional friends September 10th. Dr. F. X. Dercum acted as toastmaster.

Examination Fees not Returnable.—William McKenzie has brought suit against the Hahnemann Medical College for the return of $30 which was paid as a "graduation" fee, the plaintiff having failed to graduate. The defendant avers that this fee does not insure graduation, but only covers expenses incident to examination and commencement exercises, and under no circumstances is returnable.

Extermination of Mosquitoes.—It is stated that the State Entomologist of New Jersey will ask the Legislature at its next session for an appropriation of $10,000 for the purpose of conducting a study of the mosquito with a view to its extermination.

Western Pennsylvania Medical College.—Dr. Stewart L. McCurdy, Professor of Anatomy and Surgery in the Dental Department of the Western University, has been elected to the chair of orthopedic surgery in the Western Pennsylvania Medical College at Pittsburg. Dr. McCurdy was at one time professor of orthopedic surgery in the Ohio Medical University.

Evening Medical School.—The Medical Department of Temple College, the combined day and night school under the presidency of Rev. Russell H. Conwell, has been entirely reorganized and opened for the session of 1901-02 September 16th. The course covers five years, the entire work being given in the evening. Sessions are from 6:45 to 9:45 P. M. daily. The yearly fees are $125.

CHICAGO.

New Hospital.—The new hospital of the Sisters of Mary, built at a cost of $250,000, is nearing completion. The structure is six stories high, fireproof, of cut stone and pressed brick, with strikingly high porticoed entrances. The ground dimensions are 196 by 87 feet. The operating-rooms are on the top floor. On the north and south sides of the building are enclosed porches, which can be so heated as to be habitable the year round.

Outbreak of Anthrax.—The recent outbreak of anthrax at Palatine and its increasing prevalence in the surrounding country, which is largely devoted to dairying interests, prompted Health Commissioner Reynolds to send the Secretary of the Department, together with one of its meat inspectors, to that section to investigate the existing conditions. As a result, and at the suggestion of the representatives of the Department, the farmers throughout the infected district have formed a local association for the purpose of stamping out the disease and preventing its further spread. This association has pledged the Department that no milk or veal calves or beef cattle will be shipped from any of the infected herds. In view of these pledges, and the thoroughly reliable character of the men who made them, it was not deemed necessary on the part of the city to establish any quarantine against the food supplies from this district. It is believed that with the enforcement of the measures now under way the present outbreak will soon be under control.

GENERAL.

Morristown and Malaria.—Much comment is being aroused concerning the great prevalence of malaria in this city. The old system of water-works, with its contingent of over 200 cesspools, is supposed to bear some relation to the disease, but the wet season and the great increase in mosquitoes are not mentioned, although they are much more important factors.

State Asylum in Nebraska Burned.—The State Insane Asylum and adjacent buildings, eight in all, were destroyed by fire September 23d. Six hundred patients were in the institu-

tions at the time, three of whom are missing and supposed to have been burned to death.

The Doctors' Bills.—The sensational press is agitating the subject of the bills of the doctors who attended the late President McKinley. It is to be hoped that the niggardly policy pursued by Congress in the case of President Garfield will not be followed in the present instance.

Leprosy in Honolulu.—Leprosy is being slowly but none the less certainly eradicated in the Hawaiian Islands. Five years ago there were over thirteen hundred inmates at the leper settlement on the island of Molokai; when the annual visit was made a few days ago there were barely nine hundred. This is due to the method of treatment by isolation and quarantine.

Pasteur Institute in India.—The Pasteur Institute at Kasauli completed its first year's work on August 8th. The total number of patients received during the twelve months was 321, namely, 146 Europeans, 175 natives, of whom ninety-six belonged to the British army and twenty-five to the Native army. There was not a single failure in the treatment among the Europeans, and only two among the natives. In the latter cases the patients had been severely bitten, and arrived so late that successful treatment was impossible. There were thirty patients under treatment August 9th. The saving to the Government is very large, as no British soldiers have been sent to Paris since the Kasauli Institute was opened.

Promotion for Dr. Rixey.—President Roosevelt has notified Mrs. McKinley, through Secretary Cortelyou, that, in pursuance of the intention of the late President McKinley, and in recognition of devoted services, as well as because of eminent fitness, Medical Inspector P. M. Rixey will be appointed Surgeon-General of the Navy upon the expiration of the term of Surgeon-General Van Reypen. The Secretary of the Navy has been requested by the President to instruct Dr. Rixey to make such arrangements as will enable him to continue, if needed, his care for Mrs. McKinley between now and the time of his appointment to his new office. The naval list shows that Surgeon-General Van Reypen will not retire in the ordinary course until November 14, 1902. Dr. Rixey stands No. 28 on the list of naval surgeons. Though Surgeon-General Van Reypen's retirement from active service does not occur for more than a year, his commission as surgeon-general, which was for a period of four years, will expire on December 18, and Dr. Rixey's appointment may be expected then.

More Smallpox in Newark.—It is feared smallpox is getting a new hold in this city. There is every indication that this month will prove a record breaker. Eight patients suffering of the disease have been taken to the hospital September 18th. Among them was Health Inspector John Bull, who has since died from the disease. There have been 25 cases of smallpox so far this month. Since last February, when the first case developed this year, there have been 128 cases and 19 deaths.

Physician to the Indian Service.—The United States Civil Service Commission invites attention to the examination which will be held at various places throughout the United States on October 22d for the position of physician in the Indian Service. The examination will consist of the subjects mentioned below, which will be weighted as follows:

1. Letter-writing	5
2. Anatomy and physiology	15
3. Chemistry, materia medica, and therapeutics	10
4. General pathology and theory and practice of medicine	25
5. Surgery	20
6. Bacteriology and hygiene	10
7. Obstetrics and gynecology	15
Total	100

Information relative to the subjects and scope of the examination may be found in section 125 of the Manual of Examinations revised to January 1, 1901. The age limit is twenty-five to fifty-five years. From the eligibles resulting from this examination it is expected that certification will be made to the position of physician in the Indian Service at White Earth Agency, Minnesota, at a salary of $900 *per annum*, and to other similar vacancies as they may occur. This examination is open to all citizens of the United States who comply with the requirements and desire to enter the Service. All such persons are invited to apply, and applicants will be examined, graded and certified with entire impartiality and wholly without regard to any consideration save their ability as shown by the grade attained in the examination. Preference may be given to residents of the Indian Service district in which the vacancy exists. Persons who desire to compete should at once apply to the United States Civil Service Commission, Washington, D. C., for application forms 304 and 375, which should be properly executed and filed with the Commission prior to the hour of closing business on October 12, 1901.

Assistant Surgeon at the Freedmen's Hospital.—The United States Civil Service Commission announces that on October 29-30, 1901, an examination will be held in any city in the United States where postal free delivery has been established, for the position of assistant surgeon at the Freedmen's Hospital. The examination will consist of the subjects mentioned below, which will be weighted as follows:

1. Letter-writing	5
2. Anatomy and physiology	10

3. Surgery and surgical pathology..... 20
4. Chemistry, materia medica, and therapeutics 10
5. Bacteriology and hygiene..... 15
6. Theory and practice of medicine and general pathology 25
7. Obstetrics and gynecology..... 15

Total.....100

The examination will be divided as follows: First day, first four subjects; second day, remaining subjects. The age limit is twenty years or over. From the eligibles resulting from this examination it is expected that certification will be made to positions of assistant surgeon at the Freedmen's Hospital, Washington, D. C., at a salary of $1,000 to $1,500 per annum, and to other similar vacancies as they may occur. This examination is open to all citizens of the United States who comply with the requirements, without regard to race or to political or religious affiliations. All such citizens are invited to apply; but attention is invited to the fact that the Freedmen's Hospital is an institution for the treatment of colored patients, and it is understood to be the practice of the Department to appoint only colored persons to positions therein. Applicants shall be examined, graded, and certified with entire impartiality and wholly without regard to any consideration save their ability as shown by the grade they attain in the examination. Persons who desire to compete should at once apply to the United States Civil Service Commission, Washington, D.C., for application forms 304 and 375, which should be properly executed and promptly forwarded to the Commission.

Tri-State Medical Society of Alabama, Georgia and Tennessee.—The following supplementary list of papers is announced: Spinal Cocainization, by R. E. Fort, Nashville, Tenn.; Treatment of Acute Lobar Pneumonia, by W. S. Britt, Eufala, Ala.; Local Anesthesia as Applied to Mucous Membranes, by G. H. Price, Nashville, Tenn.; Tuberculosis: Its Relation to Marriage and Heredity, by J. A. Witherspoon, Nashville, Tenn.; The Necessity of Careful Diagnosis, Prognosis and Treatment in Some Diseases of the Heart, by L. W. Johnston, Tuskegee, Ala.; An Operation of Tubal Pregnancy Complicated with Appendicitis and Fibroid Tumors of the Uterus, by P. U. Brown, Troy, Ala.; Traumatic Injuries of the Brain, Report of Cases, by Hugh Boyd, Scottsboro, Ala.; Hernia, by G. Manning Ellis, Chattanooga, Tenn.; Surgical Shock, by D. S. Middleton, Rising Fawn, Ga.; Rodent Ulcer, by A. R. Robinson, New York; Acute Mastoiditis, by J. A. Goggans, Alexander City, Ala.

Mississippi Valley Medical Association.—The twenty-seventh annual meeting of the Mississippi Valley Medical Association adjourned at Put-in-Bay, after a most successful session, on the morning of the 14th, out of respect to our martyred President.

The following officers were elected for the ensuing year: President, S. P. Collings, M.D., Hot Springs, Ark.; First Vice-President, J. C. Culbertson, M.D., Cincinnati, O.; Second Vice-President, Paul Paquin, M.D., Asheville, N. C.; Secretary, Henry Enos Tuley, M.D., Louisville, Ky.; Treasurer, Thos. Hunt Stucky, M.D., Louisville, Ky.; Chairman Committee of Arrangements, A. H. Cordier, M.D., Kansas City, Mo.

The twenty-eighth annual meeting will be held in Kansas City, Mo., in October, 1902.

CORRESPONDENCE.

ARTIFICIAL ENDOCARDITIS—MIDDLE-EAR DISEASE—THROMBOSIS OF THE SIGMOID SINUS AND INTERNAL JUGULAR VEIN—FEATURES OF THE BUBONIC PLAGUE IN BOMBAY—GENERAL DISEASES AND THEIR INFLUENCE UPON THE FUNDUS OF THE EYE—MENTALLY-UNSOUND CHILDREN AND THEIR TREATMENT.

MENZER, at the Gesellschaft der Charité-Aerzte in Berlin, June 20, 1901, exhibited the heart of a rabbit in which malignant endocarditis had been produced by the intravenous injection of streptococci recovered from a case of malignant endocarditis in man. The cocci did not differ in any discoverable bacteriological details from such as are found in the synovia of joints after acute rheumatism and often in many cases of angina. The relation among these diseases, at least so far as this cause is concerned, is at least obvious.

TRAUTMANN read a paper on middle-ear disease and pointed out that the conditions of an external approach through the external auditory canal and an internal approach through the Eustachian tube are favorable to the onset of these troubles. Furthermore, they are unfavorable to the efficacy of ordinary preventive measures, and nullify these against such causes as currents of cold air and congestion induced by cold baths while the body is overheated. The cylindrical epithelium of the tube which extends from the posterior nares can very easily be affected and damaged by all of the acute and chronic inflammations. General health and particularly the peculiar vulnerability of children are very important factors. The active influence of bad nasal therapy, especially douches, must not be forgotten as a fruitful producer of middle-ear disease. The course of the disease is determined by the nature and virulence of the bacteria. Among 76 cases streptococci occurred in 46, pneumococci in 20, staphylococci in 20, and tubercle bacilli in 3. The dry form is not uncommon and usually after many relapses leads to various degrees of deafness. Then there are several types of exudative inflammations: the seromucous occurs usually as

the children's form, the fibrinous, as that present in nephritis and ulcerative endocarditis. The purulent types always are severe and have intense symptoms. For the treatment of otitis media purulenta are to be recommended dry gauze tamponade and free drainage by opening the mastoid cells. If this opening does not quickly close necrosis of the bony walls or of the small bones of the middle ear is probably the cause.

Stenger stated the results of his investigation of a large number of temporal bones with reference to the relation of the bulb of the internal jugular vein and the sigmoid sinus and their combined bearing upon thrombosis in each. The exact relation of these two venous channels to the tympanic cavity is a varying one. In certain cases the wall of the cavity is in part not bony, but venous, the channels lying to this extent exposed. In such individuals the danger of infection and later of thrombosis must be very great. The indications deducible from these anatomical facts are that, when the symptoms of thrombosis are present and after exposing the sigmoid sinus it is found to be free of clot, the bulb of the jugular vein should be brought to view because that may be the site of the thrombus.

M. Hahn, at the Berliner medicinische Gesellschaft, June, 25, 1901, read notes on his observations of the bubonic plague in Bombay and other localities in India during a stay there of two and a half months. The first question to be raised is whether the original defences against the plague had been stout and energetic enough, in view of the rapid and widespread advance of the disease throughout British India. The opinion of the writer was that they had not been. This has been practically admitted by the English authorities, who are, however, proceeding in Egypt with the same definite activity against it as the Germans did in Germany against the cholera in 1892. The foreign visiting physician has free access to the hospitals. The local medical authorities do not appear to suffer from any great fear of the bacilli. The attendants at the hospitals are on the whole rather indifferent. Washing facilities are the most imperfect. Common sense is very much lacking in this matter and also in the fact that rather too free access to the sick is permitted the relatives who hover about the bed, supply much of the nursing and sanitary service and often cook the food. All this certainly opens the door wide for the spread of the infection. Ordinarily the treatment is carried on by the Hindoo physicians whom the natives themselves are apt to prefer. The transportation and registration of the sufferers are very well ordered. The latter can not very well be absolutely perfect, because here and there cases are hidden. The strict isolation of the patients and the evacuation of all infected houses can not well be carried out, say the English, on account of the peculiar superstitions of the natives. True disinfection, as it is understood in Europe, can not be accomplished on account of the religion, caste customs and other social peculiarities and political organization of the country. In Egypt, at least in the harbor cities where European customs and civilization are at least familiar to and respected by the populace, it has proved quite easy. In Europe where these things are a matter of every-day knowledge, the most rigid precautions will, of course, be readily taken. The mere knowledge of one fact about the cause of a plague is not a victory over it. For example, although the cause of the malarial poisoning has been known for some time, this knowledge did not promise the means of eradicating the disease until the discovery of the means of infection in the mosquito. We are now somewhat in hope of eradicating the germ. Syphilis on the other hand is not yet assigned definitely to a bacterial cause, but the source and manner of the infection are fully familiar to all. Were it not for various difficult social problems this disease, too, could be stopped. The exact source of inoculation is not yet determined in the bubonic plague. Rats certainly play a considerable rôle at the outset, but later it is for each person some definite avenue of attack. Children appear in India to be stricken rather through the mouth. Adults usually have wounded feet from the habit of going barefoot. It is probable that a considerable decrease in the plague would occur if the Hindoos could be induced to wear shoes. The author has not found one rat dead of the bacilli. Immunity conferred by inoculation, Haffkine's method, promises well, but has not yet fully established its results. A reliable measure of protection is not yet found. A serum curative of the disease is now on the market there for which great results are claimed. If true, this serum will reduce the mortality from 90 to about 12 per cent; but, unfortunately, the universal supply of this serum is not yet possible, because the doses are so large, 100 c.c. at a time up to the total of 1500 c.c. Such large quantities are still difficult to produce. The prospects of good serum are still not bright, because this one is purely germicidal and not at all antitoxic. Under his observation the bubonic plague takes the character of a sepsis only just before death. Through the rest of its course it is purely a toxemia. An improvement in the general outlook in India can not be expected until all the hygienic factors are improved. Without a general elevation of the national intelligence this is well-nigh out of the question.

Litten, at the Verein für innere Medicin in Berlin, July 1, 1901, elucidated the relationships between some of the lesions of the fundus oculi and general disease. In 1876 he began his studies in this field, especially of the septic processes and their effects upon the eye. By this it is not to be understood purely secondary panophthalmitis, but those white streaks and spots which, alternating with small hemorrhages, appear about the papilla of the optic nerve. The conclusions he then published were that these signs appear in 80 per cent. of his total of 35 cases then recorded, that such patients almost invariably died, that the disease always ran an acute course and that the eye signs usually appeared just before death. His later ob-

servations tend to confirm the former. The eye complications occur, however, in only 30 to 40 per cent. of all cases, are not always precursors of death, do not persist after the patient has recovered from his disease, and are most common in the protracted cases. On the basis of continued observation during the last ten years the author acknowledges that these limitations are on the whole correct. If the prognostic value of their presence is also to be limited, he holds fast to the conviction that their diagnostic significance is highly important. We have to distinguish the retinal condition found in septic troubles, nephritis, pernicious anemia, leukemia, diabetes and scorbutus and to remember always the possibility of tuberculous choroiditis. Following upon his clinical observations, he made a number of pathological tests endeavoring to clear up the essence of these lesions. This seems to be an exudate into the nerve sheath. Why, however, it should always appear in the same layer and at the same point can not be fully explained.

SINELL, at the Aertzlicher Verein in Hamburg, June 25, 1901, read a paper on the mental deficiency of children and its treatment. He at first sought to define the various grades of mental incapacity and said that absolute insanity and mere feebleness of intellect must be distinguished. In the first group of patients come those who are merely weak-minded, but are still capable of instruction. The prognosis so far as the social relations are concerned and the therapeutic considerations, is much the same in all classes of cases, and the somatic importance of a differential diagnosis must not be neglected. Under idiocy, it is to be understood that there lies some severe cerebral disease in childhood or in early adolescence, which has resulted in the partial or total loss of the power of receiving and interpreting external impressions, although not in the loss of many of the ordinary mental processes of life. The final outcome of the lesions is more or less disturbance of the motor, sensory and intellectual processes. Only the most rigid and careful examination will reveal the differential diagnosis between true idiocy and mere mental insufficiency. Between these two conditions there are very many transitional stages. The importance of training-schools for these poor children can not be overestimated. The most essential point of all is that this condition be early recognized. As a rule, such children suckle poorly, cry almost continually, are nervously restless and excited, often blind and deaf or appear so. Under imbeciles, on the other hand, one must not include a mild degree of idiocy. Here is often found some moral defect or antisocial element. For the detection of such imbeciles one must investigate the existing degree of the power of attention, spontaneous or voluntary, color sense, hearing, taste, smell, etc. Deficient muscular sense is the cause of the awkwardness and muscular weaknesses of these patients. Many times the bodily origin of these nervous troubles is adenoid growths, whose removal may be promptly curative. The therapeusis is for the merely feeble-minded and approved home-training, with much patience and the aim of developing the afflicted. Occasionally an asylum is necessary where the same processes are to be followed. Special effort toward the development of the perception, attention, speech and muscular systems must be made. Rest, freedom from nervous irritation and avoidance of bodily punishment and maintenance of good environment are all to be observed. One must always remember that these conditions as such are really totally incurable. The idiot may, however, by instruction, be developed so that he can take care of himself and respect the rest of the community, but the imbecile can never be trusted and must therefore always be confined.

OUR LONDON LETTER.

(From Our Special Correspondent)

LONDON, Sept. 14, 1901.

THE NEW SCHEME OF ARMY MEDICAL REFORM—A VICTORY FOR THE DOCTORS.

THE Government scheme for the reform of the Medical Service of the Army has not yet been promulgated, but it has been passed by the Treasury, which is generally the greatest obstacle to delivery in official parturition. Only a general idea has so far found its way to any one outside the charmed circle of the War Office. I am, however, by special grace—whether of God or the (printer's) devil, I will not say—in a position to give you an outline embracing all the essential features of the scheme. So slow are the movements of our Government that it is probable enough that your readers will know the details of the scheme some time before they come to the knowledge of those most concerned here.

I should say first of all that the scheme is in the nature of an agreeable surprise. As has been said in previous letters, Mr. Brodrick, the Secretary of State for War, has on several occasions been distinctly unsympathetic in his references to the medical officers of the Army, and has even seemed sometimes to go rather out of his way to treat them with hardship. It was therefore expected that his scheme would be of a character that would make it unacceptable to the medical profession. I am bound to say, however, that it bears every sign of having been inspired by a real desire to satisfy the legitimate demands of the profession, while securing the efficiency of the service. The fundamental feature of the scheme, in which it differs from all the Royal Warrants on this subject previously issued, is that the service will in future be controlled by an Advisory Board. This means that instead of a Warrant, which may be made a dead letter in practice by the perverse ingenuity of the War Office or even by the personal whim of a commanding officer, the medical service will be controlled by a living organism whose special function it shall be to administer the scheme in the sense intended by its framers, and to modify its details as experience may suggest or special circumstances may re-

quire. The controlling power in the administrative machinery of the Army Medical Service will therefore be sufficiently elastic to adapt itself readily to the ever changing conditions with which it has to deal. Of course, everything will depend on the constitution of the Board. If it were to be merely a select body of more or less ornamental dummies, like Napoleon's senators, who should simply prophesy smooth things to the Secretary of State for War, it would be no improvement on the existing system. But pains have been taken to to make the composition of the Board representative not only of the service itself but of the civil profession. The Board is to consist of the director general and the assistant director general of the service; of an officer of the Royal Army Medical Corps with special knowledge of sanitation; an officer of the same Corps possessing special knowledge of tropical diseases; two civilian physicians and two civilian surgeons chosen by the Secretary of State; and one representative of the War Office. Of this Board the director general is to be chairman and is to have a casting vote in all questions where opinions are equally divided. If he is a strong man, this will leave him practically master of the field. The civilian members of the Board are to be chosen from among the staff of one of the great teaching hospitals; they must not be less than forty-five years of age or over sixty. In this way it is hoped to exclude the fossil element which is so apt to paralyze the efficiency of boards of all kinds. The Board is to meet fortnightly, and three members at least are required to form a quorum, one of whom must be a civilian. The constant presence and living influence of the civilian element is expected to keep the military element, which generally shows a tendency to early ossification of the intelligence, up to the mark.

Through this Advisory Board the Medical Service of the Army will be governed by the Secretary of State. It will keep a watchful eye on all military hospitals, and on individual officers; it will control examinations and personally inspect all candidates, to see what manner of men they are, before they are admitted to the service. It will receive reports on the working of the service in every detail, and make representations to the Secretary of State on these reports and on all such other matters as it considers important for the efficiency of the service. Though the Board will be only "advisory," it will scarcely be possible for even the most autocratic Secretary of State to treat its "representatives" lightly; if he does, he can be called upon to justify his action in the House of Commons. On the other hand, it will be out of the power of the most militantly military Commander in Chief to pursue the policy of the Duke of Cambridge and Lord Wolseley, to whom it seemed to afford a special satisfaction to snub "the d—d doctors." The dislike of the former for the doctors is believed to have had its origin in the fact that during his inglorious career in the Crimea his life was saved by an army surgeon who took command at a critical moment and brought His Royal Highness, rather the worse for wear, out of the fight. Wolseley's hatred of the medical officers is particularly remarkable in the view of the facts that he had a brother in the department, and that the wars in which he won his laurels were really victories of sanitary science. Henceforth the Commander in Chief, if he allows himself to show the insolence of office upon occasion, can speedily be brought to book.

Admission to the medical service will still be by examination, but instead of being worried with questions on anatomy, zoology, etc., the candidate's knowledge will be tested clinically and practically. Promotion in the junior ranks will be by examination, for which six months' special preparation in a hospital fully equipped with laboratories, etc., will be compulsory. In this way every officer before attaining the rank of major will have gone through at least a year's extra study in a place where all the means of furnishing knowledge and practical skill to the highest point are available. Beyond the rank of lieutenant colonel promotion will be entirely by selection. This is a further indication of the determination, as far as is possible, to weed out incompetence and fogeyism. Encouragement is to be given to men to make themselves specially proficient in operative surgery, laryngology, dermatology, etc. The pay of all ranks is to be materially increased from the youngest lieutenant who, including allowances of one kind or another, will get $1,850, up to the director general, who will get $10,000 a year.

The scheme of reform includes the establishment of a great military hospital with not less than 500 beds in London; and a Medical Staff College, also in the metropolis. Here as a rule officers studying for promotion will go through their special training.

On the whole it may be said that by the new scheme everything asked for by the medical profession has virtually been conceded. The rank and titles remain as they are; the pay is increased to an extent sufficiently to remove this particular grievance; opportunities are given to the officers of the service to keep their professional knowledge up to date; and they are no longer to be at the mere mercy of the War Office, which has neither a body to be kicked nor a soul to be damned. The Advisory Board can be called to account jointly and severally by the press; and the caprices and prejudices of military officers from the Commander in Chief to the youngest captain can be effectually held in check. To medical journalists this unconditional surrender of the military authorities is particularly gratifying, for the victory is due almost entirely to the medical press.

Bellevue Hospital Exonerated.—Bellevue Hospital authorities were exonerated from blame for the death of John Chrystie in the pavilion for the insane attached to that institution on June 18, as a result of an investigation held Wednesday before Coroner Bausch and a jury.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Fifty-first Annual Meeting, held at Philadelphia, September 24, 25, 26, 1901.

FIRST DAY—SEPTEMBER 24TH

The meeting was called to order by the President, Dr. T. D. Davis, of Pittsburg.

The opening session was devoted to the reports of committees, new business, etc. Resolutions expressing sympathy for Mrs. McKinley were adopted.

Address in Otology.—This address was delivered by Dr. E. N. Buckman of Wilkesbarre. The speaker mentioned the progress in this branch during the last six years, stating that mastoiditis was considered a very serious disease when he began practice, now radical operations are so successful that abortive treatment is not long kept up in any case. This is one of the most satisfactory conditions the aurist has to treat. The least satisfactory and one which shows the least progress during the last five years is tinnitus. The cause is not definitely known, but there is slowly increasing deafness where tinnitus is the chief symptom. Often there are constrictions in the Eustachian tube. Success in treatment is not marked in many cases Bougies may be used, but they are apt to break and do not remove the constriction. Massage benefits some cases. To be useful it must be vigorous. During the past four months Dr. Buckman has used electricity, mainly in obstinate cases not benefited by other treatment. The time is too short to admit of definite conclusions, but he thinks the claims made for electricity are not exaggerated. It will give good results in many cases. Success in treating these cases depends more on how remedies are used than on the means employed.

Some Aural Complications of Influenza.—Dr. S. MacCuen Smith of Philadelphia spoke on this subject. Inflammation of the middle ear due to influenza is noted for the intensity, rapidity, and virulency of its action. The hemorrhagic form is more frequent than those from other causes. Mastoid implication and irritation are present in all severe cases. Two cases of primary mastoid abscess have been seen. In influenzal otitis suffering continues after spontaneous rupture of the membrani tympani. A bacteriological examination of all ear discharges is of great value, although other bacilli may take the place of the exciting cause after some time. The character of the infection cannot be judged from the odor of the discharge as is sometimes attempted. Dr. Smith has seen and studied particularly 23 cases and he enumerated some of the general characteristics. Nine were of the hemorrhagic variety. Fourteen terminated in spontaneous rupture of the membrane after forty-two hours, the pain continuing afterward for from twenty-four to sixty-four hours. In six cases the membrane was incised early in the attack with prompt relief of pain. Prophylaxis is of utmost importance in cases of influenza and if aural complications do arise they should be treated boldly. Rest in bed with a milk and broth diet (or, better still, fasting for two or three days), diuresis and diaphoresis are the best measures that can be instituted. Influenzal earache yields stubbornly to hot applications, but hot antiseptic solutions may be tried. Prompt incision of the membrane should be made when any distension is noticed.

Incudectomy for Progressive Hardness of Hearing, Tinnitus Aurium, and Ear Vertigo.—Dr. Chas. H. Burnett of Philadelphia said that progressive hardness of hearing is caused by atropho-neurosis of the muscular structures in the Eustachian tube, nasopharynx, and middle ear. There is finally caused an impaction of the stapes in the oval window. In ear vertigo there is contraction of the tensor tympani muscle. The surgical treatment recommended aims to overcome this retraction of the tensor tympani and ossicles. Surgical intervention often wards off the occurrence of the same process in the opposite ear.

Reasons for Early Operation in Acute Mastoiditis.—Dr. Wm. H. Dudley of Easton said that the experience of physicians should make a paper on this subject unnecessary, but such is not the case. Several cases were detailed to show the evil consequences of deferred interference.

In the discussion of these papers Dr. Burnett said, in answer to the question as to what symptoms in mastoiditis called for operation, that there were three, namely, pain, pyrexia, and prolapse. The latter refers to prolapse of the upper, posterior part of the membrani tympani and the adjoining external auditory canal.

Ocular Affections in Childhood Associated with Impaired General Nutrition.—This paper was read by Dr. S. D. Risley of Philadelphia. He said that the true condition in these cases was generally not recognized until a thorough ophthalmological study was made. This is a reason for speaking of them from the ophthalmological point of view. Two cases were cited. In both there was astigmatism and changes in the fundus. Correction of the eye defects combined with internal treatment, removal from school, etc., effected a cure in both. The clinical picture in all such cases is practically the same—impaired vitality, headache, general malaise, precarious temper, etc. With these is combined some form of asthenopia. A question to be solved is to what extent eye strain at school affects general nutrition.

Gumma of the Ciliary Body.—This interesting case was reported by Dr. Edward Stieven of Pittsburg. The patient was a woman who had been treated for tertiary syphilis and who supposed herself cured. After a time she reappeared with involvement of the nose and of one eye. This was in December, 1900. Ex-

amination of the eye then and subsequently showed a gumma of the ciliary body with involvement of the lens and vitreous, sight being finally lost. Enormous doses of potassium iodide, as high as 240 grains three times a day, and large doses of strychnine were given. Improvement began and by July, 1901, there was vision of six-eighths, the gumma having apparently entirely disappeared. The inference is that prognosis in these cases should not be hopeless.

Contagious Diseases of the Eye and Their Treatment.—In this paper Dr. S. Lewis Zeigler of Philadelphia reviewed the varieties of contagious eye diseases and pointed out their treatment by general practitioners.

Address in Mental Disorders.—This was delivered by Dr. Robert H. Chase of Philadelphia, who chose as his subject "Paresis From the Standpoint of the General Practitioner." It is a mistaken idea to think that this affection is to be dealt with by the specialist alone. The general practitioner sees the cases first and at the time when treatment is of avail—early in the disease. In forming the diagnosis it is best to take the patient unawares. At first he is conscious of ill feeling; afterward he feels well. Theft and acts of indecency are often committed years before the diagnosis is made from other symptoms. Amnesia is often shown early. Physical signs are indefinite. An outline of treatment for the early stages is to remove the cause if possible, prohibit coition, and the use of alcohol, reduce the patient's work, and place him under favorable hygienic conditions. Partial rest treatment and hydrotherapy are valuable in some cases. Rest and removal from daily surroundings should be advised in cases which are only suspected. An additional duty of the physician is to prevent marriages that would cause hereditary tendency to the affection.

Two Cases of Muscular Dystrophy in Brother and Sister.—Dr. A. A. Eshner of Philadelphia briefly detailed these cases. Both are typical cases of the disease. Interesting points are that the father received an injury to the brain by a fall when sixteen years of age and that there is a paternal history of obesity, four of the father's sisters each weighing more than 220 pounds. Of Dr. Eshner's 20 cases, 2 showed the condition at birth, 8 within five years, and 10 within ten years. There were 16 males and 4 females.

Prognosis in Neuritis.—This subject was briefly presented by Dr. F. Savary Pearce of Philadelphia. Pressure neuritis is to be differentiated from occupation neurosis. The prognosis is more favorable in the former, but relapse is apt to recur. Septic neuritis is usually favorable, nerves showing a certain immunity to pus. The prognosis in alcoholic and metallic neuritis is uncertain owing to relapses. In diphtheritic neuritis the affection seems to be less severe in those cases which have not been given antitoxin. Gonorrheal neuritis is usually local and chronic.

Cases of Hysteria.—Dr. Edward E. Mayer of Pittsburg cited cases to illustrate the difficulty of diagnosis. Some points emphasized were that hysteria is always a psychic disease; that non-hysteric stigmata of degeneration are generally found in hysterical subjects; that the prognosis is less favorable as these stigmata are more pronounced; that the treatment is to remove the prime factor.

The President's Address was delivered Tuesday evening, Dr. Davis chose for his subject "The Pioneer Physicians of Western Pennsylvania." The departure from the usual custom of treating a purely scientific subject was well received by the Society. Dr. Davis' description of the early history of Pittsburg and vicinity and its physicians was thoroughly enjoyed by all who were fortunate enough to hear him.

SECOND DAY—SEPTEMBER 25TH.

Address in Medicine.—This address was delivered by Dr. John B. Donaldson of Canonsburg. It was not too optimistic as regards the present condition in the State. The speaker said that but little had been done by the State in preventive measures against tuberculosis or in caring for the indigent tuberculous. They need not be sent South or abroad. Pennsylvania's own hills are ample. The existence of slums in the large cities is a blot on the age. They can be done away with whenever it is demonstrated that it will pay. Disease is not fought at home as we fight it abroad—at Havana for instance. Filtration is retarded by schemes of contractors. "White wings" clean the avenues, but alleys are neglected. Of great promise is the raising of the standard of medical education. Dr. Donaldson prophesies that ere long we will see an end of the so-called "schools" of medicine, and all physicians will work alike for one end—the eradication of disease.

Gastroptosis and Its Treatment.—This was the subject of a paper by Dr. J. Dutton Steele of Philadelphia. Gastroptosis may exist absolutely without symptoms. When present they are generally those of gastric motor insufficiency. A study of 50 cases showed the order of frequency to be (1) gastroptosis and dilatation combined; (2) dilatation alone; (3) gastroptosis alone. Females are most affected and the condition most frequent in males is simple dilatation. Pressure from above is the most frequent cause of the condition. Any method of examination for diagnosis except that of inflation is unreliable. Tartaric acid and sodium bicarbonate are occasionally used for inflation, but the stomach tube is essential for thorough examination. Air can be forced in by the bulb of an atomizer. The stomach can be mapped out in every case. The air should be allowed to escape before withdrawing the tube. Examination of the gastric contents is of no value in diagnosis. Treatment consists in proper diet, lavage if there is retention, and mechanical support. For the latter an elastic bandage is best and it should be held in place by

perineal straps. Pads should also be bound on the abdomen. The stomach should be distended with air after the belt is applied to see if it is in proper position.

Movable Kidneys; Their Effect Upon the Gastric and Intestinal Functions.—Dr. Boardman Reed of Philadelphia stated that in many cases all the abdominal viscera were involved together, being movable and prolapsed to some degree. The etiology of movable kidney is lack of development of the muscles of the abdomen and unhygienic methods of dress. Pregnancy has nothing to do with the condition. Digestive disturbance is the most prominent symptom. Movable kidneys often act as a stimulant to gastric secretions and sour eructations are caused. Insomnia and constipation are also symptoms and neurasthenia is almost sure to follow. As to prognosis a certain number of cases can be cured without surgical intervention if the patient can afford the treatment. If the kidney is tender or painful, confine the patient to bed from two to six weeks, apply retentive apparatus, and fatten and build up in every way. Stubborn cases often develop hyperchlorhydria and intragastric faradization may be needed. If further trouble persist nephropexy may be done.

Discussion.—Dr. Gibbon of Scranton stated that the use of pads was a mistake as they may cause appendicitis. The reversed corset is the only exterior appliance that should be used. If not effectual, operate and at the same time remove the appendix.—Dr. John G. Clark of Philadelphia changed the subject of his paper and spoke on the treatment of movable kidney. The more conservative methods should be first tried. When there is separation of the recti muscles he is in favor of Webster's operation, *i. e.*, removal of the fascia and uniting of the muscles.

Infective or Malignant Endocarditis.—Several cases of this condition were reported by Dr. A. O. J. Kelly of Philadelphia. Etiology and diagnosis were the points treated. Acute endocarditis is believed to be a single process. Gradations depend upon the virulence of bacteria present and the resistance of the individual. The name endocarditis is a misnomer. Bacteria are found in secondary lesions and in emboli and the blood. The condition is properly pyemia or bacteremia. Toxin of the bacteria is believed to be the only etiological agent in some cases, as the bacteria themselves are not found on the valves. Three factors are of value in making the diagnosis: (1) The leucocyte-count, including differential; (2) bacteriological examination of the blood; (3) symptoms referable to the heart, the so-called arythmic disturbance. In the discussion Dr. J. M. Anders emphasized the importance of applying modern methods in the study of these cases. In contradistinction to some other speakers, Dr. Anders believes that some value must be attached to the occurrence of murmurs. These, with the occurrence of embolic phenomena and the presence of bacteria in the blood, serve to make the diagnosis. In supposed easy cases the trouble should be taken to eliminate other conditions which simulate it, notably typhoid fever.

A Few Notes on the Salts of Sulpho-Carbolic Acid.—This was the title of a paper by Dr. Edgar M. Green of Easton. The value of sodium sulpho-carbolate in arresting fermentative changes in the gastro-intestinal tract was emphasized. Acetanilid and the drug mentioned work well together in alleviating headaches. A smaller dose of the former will give the same effect when combined with the sodium salt.

Primary Abdominal Tuberculosis.—This paper was presented by Dr. Lawrence F. Flick of Philadelphia. Dr. Flick believes that 25 per cent. of all cases of tuberculosis begin in the belly. The diagnosis is exceedingly difficult. It is for the abdominal surgeon to furnish a symptom-complex by which the disease can be recognized. In all cases of chronic indigestion, persistent backache, diarrhea, leukorrhea, etc., when accompanied by loss of weight and strength, tuberculosis should be suspected. Treatment is unsettled as yet. Opening the abdomen cures some cases. A general building-up treatment is indicated. The use of iodoform is worthy of a trial.

Discussion.—Dr. Joseph Price of Philadelphia said that in former years surgeons blundered into the treatment of these cases, the diagnosis not having been made, the operation possibly being done for some other condition. Statistics of results by pioneer surgeons were favorable and for a time he has not refused to open an abdomen for tuberculosis. Surgeons have always made the error of being afraid of adhesions following operation. Iodoform is of great value in these cases and the whole peritoneum and its contents can be made yellow with it and no toxic effects follow. In one case only enough iodoform to cover eight inches of intestine was on hand. A second operation was necessary later and showed the eight inches of gut in a healthy condition, the remainder being covered with tubercles and adherent as before. Abdominal tuberculosis is a condition that justifies intraperitoneal liberties never before taken if the exigencies of the case demand it. The more the abdominal contents are manipulated and exposed and douched the better will be the result. The indications then are for (1) early operation; (2) free use of iodoform; (3) drainage.—Dr. Mordecai Price is sure that he has seen cases of abdominal tuberculosis caused from the use of milk from an infected herd. Early exploratory operation in doubtful cases is indicated.—Dr. James Tyson stated that the tuberculin test is the most infallible aid to diagnosis that we have. It is perfectly safe and in his experience almost infallible.—Dr. S. Solis Cohen said that iodoform was a most valuable agent in the treatment of tuberculosis. It can be prescribed internally if care is taken to increase the dose very gradually. From three to four months should be taken to reach the maximum dose. He believes that Theobald Smith is entitled to much more credit for his

statements in regard to human and bovine tuberculosis than is Robert Koch. It would be a serious mistake for physicians, health boards, etc., to take the view that infected meat and milk are not dangerous when our present knowledge is not more definite.

Address in Hygiene.—This address was delivered by Dr. E. B. Borland of Pittsburg and was a running comment on the present-day status medical and sanitary affairs. The great work done in Havana and Santiago was a triumph of modern hygiene, but the death of so many soldiers during the recent war shows the need of more hygiene in the curriculum of medical schools and its promulgation among the people. The prevalence of smallpox now is due to the work of silly and ignorant antivaccinationists and also to the failure of authorities to provide special hospitals. Special hospitals for smallpox, scarlet fever, and diphtheria cases should be provided in every town of over 1,000 inhabitants. Girls should be taught cooking and the hygienic preparation of food. Vile advertising in papers should be stopped. The prevention of tuberculosis is a vital problem. Stoppage of the spitting habit and notification of tubercular cases are to be commended.

The Histories of Three Accidents in Tapping the Chest.—This was the title of a paper by Dr. J. C. Lange of Pittsburg. The first was instant death of a man, seventy-six years of age, from paralysis of the heart the moment the needle was introduced. The patient had albuminuria, arteriosclerosis, and dropsy. No clots were found in the heart postmortem. Case II. was a man, twenty-three years of age, who had a gush of blood (12 ounces) from the trachea during the tapping and hemoptysis for several days. He finally recovered after two tappings and the drainage of an empyema later. Case III. was a female, fifty-eight years of age, who had pleuritis as a complication of biliary cirrhosis of the liver. She also had hemoptysis during, and for some days after, the tapping.

Reforms in Medical Legislation.—Dr. H. M. Shallenberger of Rochester read a paper on this subject. The paper was an arraignment of the existing policy of the majority of medical schools and suggestions for their revision.

The Vermiform Appendix.—Dr. Edmund Holmes of Philadelphia exhibited specimens of colon and appendix showing various forms of the latter organ. In 96 of 110 cases the right lobe of the cecum was larger, causing the appendix to appear nearer the ileum. Forcible distention revealed a tendency to revolve around the ileocecal valve. The left side then is the place to explore for the appendix when it is not readily found. The appendicular artery is usually single, but there can be two or more. The length or displacement of the organ may account for the anomalous symptoms in some cases. The psoas magnus muscle may lead one astray in diagnosis at times.

(To be Continued.)

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held June 10, 1901.

The Vice-President, William McCollom, M.D., in the Chair.

Degenerated Nerve-Fibers of Sensory System.—Dr. M. G. Schlapp presented microscopical sections of different parts of the nervous system, showing degeneration of nerve fibers throughout the whole sensory nervous system (column of Burdock and Gall, roots of trigeminus, vagus, glosso-pharyngeal, and acoustic), produced by the indirect effects of an intracranial growth. The degeneration was confined to the intramedullary fibers, and extended only and exactly to where the sheath of Schwann begins to surround the extramedullary fibers. Dr. Schlapp thinks the sheath of Schwann acts as a protecting sheath to the myelin substance; hence the degeneration of the myelin substance is confined to the intra-medullary fibers, having no sheath of Schwann, and that the degeneration primarily is confined to the myelin substance, the effect, no doubt of the direct action of the intracranial pressure or toxic substances (or both) on the myelin substance, and not secondarily through the trophic centers of the fibers degenerated.

Glioma.—Dr. Schlapp also showed a specimen of a glioma stained for about one minute in Delafield hematoxylin, washed in water, and then stained in a solution of acid rubin (Kulschitsky). The combination of these two stains gives a beautifully clear definition of the glia cell with its nucleus and the fibrillæ. The nucleus is stained blue, the cell-body and fibrillæ red.

Pyosalpinx Involving the Appendix Vermiformis.—Dr. Berg presented the right tube and ovary of a patient which were removed for pyosalpinx. When admitted to the hospital the case appeared to be one of ordinary appendicitis with abscess formation, but when the abdomen was opened it was found that the condition was one of pyosalpinx, and that the appendix was involved only by continuity. The woman made a good recovery.

Growth of New Bone from Periosteum.—The first paper of the evening was read by Dr. J. H. Branth. He said that more than twenty years ago he had removed more than one-half of the inferior maxilla, with a view to having a resulting regeneration of the bone from the periosteum. A number of operations were undertaken to remove sequestrated bone, and it took over a year to close the last sinus. One year later but little scarring was visible, and from the contour of the face it would not have been suspected that so much bone had been removed. On touch one could feel that bone substance had been reproduced. Dr. Branth then presented a patient from whom, in 1884, he had removed nearly all of the os

calcis. He took out a large necrotic mass and curetted the empty periosteal sac. The anterior articular part of the bone was healthy and was left remaining as a shell-like body. The result was most gratifying. In the speaker's experience this principle of subperiosteal bone surgery for reproduction of bone has been applied with varying success. Even where failure resulted nothing was lost, for at a later stage an operation for removal of the entire inflamed part could always be undertaken. In order to determine the application and limitations of such procedures, he took up the consideration of some features of growth, nutrition, repair, degeneration and necrosis, as having to do with periosteum and bone substance. From this study it was apparent that subperiosteal surgery, generally speaking, is limited to cases of necrosis, and does not include in its range cases in which malignant constructive or destructive cell-life exists. After necrosis of a part of a bone has resulted it may occur that the periosteum, having been lifted off the bone, may deposit bone-cells on its under surface and so build a bridge, as it were, over the necrotic substance for some distance, while at some small outlet the débris makes an exit. Such a condition will not permit healing until the sequestrum has been removed, which Nature alone accomplishes by a slow process of disintegration into débris that becomes portable through the avenues of exit. The indications for treatment are plain. The surgeon should aid Nature to get rid of the dead bone substance, but operative interference should be delayed until the line of demarcation between living and dead tissues can be detected, and then the dead bone can be removed piecemeal from the openings, which may be enlarged by incisions. There must be a limited osteitis during the repair of a fracture, which repair is primarily and for the most part accomplished by the periosteum; and later, when the medullary canal is re-established, the endosteum will also contribute to the restoration to the normal condition. In order to secure the best results in amputations the surgeon should take pains to cover the end of the bone stump with a flap of periosteum. In operations for cleft palate we depend on transplantation of muco-periosteum for material to close the gap. While the principle of reproduction of new bone from periosteum is of comparatively limited application, in suitable cases it may be carried out with a fair prospect of success, especially where delay is possible.

Cerebral Concussion, with Retinal Changes.—Dr. L. A. W. Alleman read a paper on the above subject. Retinal changes have not been frequently observed, and the case on which the paper was based presented some very unusual features. Mr. X., a young man in perfect physical condition and a prominent member of the football team of one of the great universities, had been under observation since January, 1897, when he was first examined and given a correcting glass. On October 28, 1900, the day after an intercollegiate game in which he had taken part, he presented himself, complaining that for some time he had been suffering from discomfort in reading, similar to that experienced before using glasses and that he was annoyed by a blur before the left eye, of recent development. His corrected vision, which had been 20/15 on all previous examinations, was found to be reduced to 20/20 in the right eye and 20/100 in the left, and could not be improved by a change of glass. Ophthalmoscopic examination: Scattered about the fundus of both eyes were pigment spots and degenerative plaques of small size, which suggested old hemorrhages. The nerve margins were indistinct and the retinal vessels markedly tortuous. In the right eye, midway between the macula and disc, was an area showing pigment absorption and indefinite retinal changes, and in the left, a slight haze extending over the entire fundus and attributed to retinal edema. On the following day a small fluffy spot, just above the fovea, could be seen in the left eye, even with an undilated pupil. This retinal picture in a patient in such apparent health was alarming, since, on account of previous examinations, an old lesion could be excluded. Incidentally it was discovered that in the football game the patient had received a rap on the head, which had "knocked him out" for a few moments. He said that he had seen double and had been dazed for the remainder of the game. This accident was of so little importance, in the young man's judgment, that he had forgotten it when questioned about an injury. He had frequently received many such raps and thought nothing of them. This discovery suggested a possible explanation of the retinal changes and of the old hemorrhages, but a thorough physical examination was requested. Shortly afterward vision was found to be normal in both eyes. This seemed to show that the impairment in the latter had been due to concussion (so-called commotio retinæ), and not to the minute lesion at the macula, which was still perceptible. The physical examination proved entirely negative. The patient was absolutely sound and showed none of the minor evidences of vascular disease. In discussing the case the author referred to the remarkable ability acquired by athletes to withstand and react from injuries which would be disabling or well-nigh fatal to the ordinary individual. A week later an examination showed vision to be 20/15 in each eye. The right fundus was entirely normal, save the old pigment spots. In the left the picture was clear and bright. The tortuosity of the vessels was much diminished and now confined to the larger vessels. The spot in the macula had entirely disappeared.

Concussion and Eye Lesions.—While some authors explain all eye lesions following concussion of the brain as the result of either meningitis or fracture, this is manifestly impossible in the cases showing ocular symptoms immediately after the injury, and making a complete and rapid recovery. As most writers restrict the term commotio retinæ to the result of direct violence to the globe, we are obliged to place cases due to head injuries in a separate class. The fact that the condition has not been discovered oftener does not argue that it is of rare occurence, for the majority of the cases would ordinarily escape observation. The question suggests itself whether the spots occasionally met with in otherwise healthy retinæ, which point to old hemorrhages, may not be the mark of a previous traumatic hemorrhage. Holt and Neal have reported a series of cases of concussion, some of which were due to indirect violence. From these and from a few isolated cases we can make out a fairly distinct clinical picture of retinal concussion form indirect traumatism. Recovery is usually rapid and complete, but there is always the possibility of permanent impairment of vision. The cases due to indirect violence seem to be practically identical with those of concussion of the ball, when the blow is of only moderate severity. As no entirely satisfactory explanation has as yet been offered of the manner in which concussion gives rise to the retinal complication, Dr. Alleman was inclined to agree with Seely in throwing the burden on the neurologist.

Spurious Cases.—Dr. Alexander Duane said that genuine cases of the kind described by Dr. Alleman were very rare. Spurious cases are not uncommon. They comprise, first, those in which the eye itself has been directly injured by the force causing the concussion of the brain; second, those in which a disturbance of vision of a purely central origin, a hemiopia, for example, is present; third, cases, in which the disease of the fundus really antedated the concussion, but was latent or only slightly manifest.

Conditions Present in Genuine Cases.—The conditions obtaining in the genuine cases include commotio retinæ, as in Dr. Alleman's case (although commotio retinæ is much oftener due to blows upon the eye itself), hemorrhages, and, as isolated curiosities, retinitis and rupture of the retina. There may also be produced, as in one case of his own, a condition simulating retinal thrombosis. This is probably due to contraction of the retinal vessels resulting from the sudden reduction of the cerebral circulation. If the blood-vessels are already abnormally narrow, such contraction, as has been proved, may be extreme enough to cause the symptoms of a permanent occlusion. As regards commotio retinæ he thought the theory of a sympathetic involvement explained it most plausibly.

Case of Cerebral Concussion and Hystero-Epilepsy.—Dr. W. B. Noyes read this paper, which will appear later in the MEDICAL NEWS.

NEW YORK ACADEMY OF MEDICINE.—SECTION ON ORTHOPEDIC SURGERY.

R. H. Sayre, M.D., Chairman *pro tem.*

Correction of Deformity.—Dr. Royal Whitman presented a patient upon whom he operated in 1897 for the correction of a very marked anterior bowing of both legs. The operation was an osteotomy of the tibia, fracturing of the fibula, division of the tendo Achillis and direct forcible correction of the deformity. He presented the case to show the good results; the operation seemed preferable to cuneiform osteotomy as it resulted in lengthening the bone somewhat.

Rotary Lateral Curvature of the Spine.—Dr. Whitman showed a girl with marked lateral rotary curvature of the spine. Four years previously he had treated her for clubfoot and had not seen her since. He advised for this patient manual correction and fixation in plaster jacket. He called attention to the complete range of dorsal flexion present in the foot. His treatment had been manipulation and the plaster bandage.

Dorsal Pott's Disease.—Dr. Whitman showed a boy treated for Pott's disease in the dorsal region with his anterior shoulder-brace in connection with the ordinary back-brace, and called attention to the fact that there was no forward inclination of the shoulders nor flattening of the chest, as is usually the case in deformity of this region.

Ankylosed Elbow-Joint.—Dr. W. R. Townsend showed a man with angylosed elbow-joint flexed just short of a right angle, to show the great range of motion preserved to an arm where the fixation of the elbow had occurred in a favorable position.

Pott's Disease Without Deformity.—Dr. Townsend presented a second patient who two years prior to his seeing him complained of pains of a girdle character in his back and abdomen. There was stiffness of the lower portion of spine, but no evidence of deformity. Diagnosis of Pott's disease without deformity was made and a plaster-of-Paris jacket applied. The jacket was removed after four months at patient's request; all pains had disappeared, and there was a question as to possible error of diagnosis. The patient subsequently returned with a large cold abscess in the left lumbar region, with psoas contraction. The man felt no pain and was unwilling to have jacket reapplied. The abscess and spinal stiffness made the diagnosis of Pott's disease certain. Dr. R. H. Sayre said he had under observation a case similar to the one of Pott's disease shown by Dr. Townsend. The patient had girdle pains, pains down the thighs, difficulty in bending and great pain on being jarred; no deformity. Diagnosis of Pott's disease made and plaster jacket applied. Some-

time later the patient developed paralysis of both lower extremities. After a year the paralysis disappeared and a large pelvic abscess developed which was opened in the inguinal and lumbar regions. Later there formed in the opposite side another abscess which was opened. At present there is a very slight irregularity noticeable at the fourth and fifth lumbar vertebræ. The pressure of the abscess accounted for the paraplegia.

Fracture of the Neck.—Dr. Sayre showed a man who some months previously had fractured his neck by falling. Following the injury, he had paralysis of the lower extremities and partial paralysis of the upper extremities with no control of bladder or rectum. When seen by Dr. Sayre two months after the injury, the patient's neck was rigid. A diagnosis was made of fracture with dislocation of the third and fourth cervical vertebræ—verified by use of the X-ray. The treatment consisted in getting the head into a good position and applying an apparatus to support the head and hold the neck. The man had been under treatment three months and movements of head were good; apparatus would be discarded. He cited other cases, and said splints were frequently removed from fractures too soon and before good osseous union had taken place.

Deformities of the Elbow-Joint.—Dr. Samuel Lloyd read the paper of the evening, entitled: "The Operative Treatment of Deformities of the Elbow-Joint Resulting from Traumatism." He said three things were recognized in fractures into the elbow-joint: First, it is not always possible to tell even under an anesthetic and with the most careful examination just what the joint injury is. Second, it is not always possible to replace the fragments even approximately. Third, ankylosis results in certain cases in spite of any plan of treatment. All fractures involving or in vicinity of the elbow-joint should be examined under an anesthesia, and the fragments placed in apposition and the limb dressed in a position that enabled the operator to retain them in place most efficiently. He favored flexion. He was decidedly opposed to passive motion so much advocated by the older surgeons, believing that this caused an increase of callus and consequent diminished range of motion. Any passive motion in an elbow-joint until after the bone was firmly united was meddlesome surgery. If, when the splint was removed, motion did not return promptly by active motion (an attempt on the part of the patient to use it regularly) the deformity should be examined. If the joint did not yield under an anesthetic, then the difficulty was probably due to obstructing callus or a displaced fragment. He believed the ankylosis or limitation of motion due to bone and not to fibrous adhesions, provided there had been no septic complications. While his first operations and conclusions antedated the use of the X-ray, the latter had been corroborated by an extensive use of the X-ray. The overproduction of callus was a constant danger of producing ankylosis and was increased by any motion of the fragments during the period of union; provisional callus was objectionable, bone united in the same manner as the soft tissues, with but little granulation tissue, if firmly held together. The X-ray has been somewhat disappointing in solving all the difficulties of fracture work, since it gives only a shadow of the real object. The X-ray, however, so frequently illustrating dislocation complications, had emphasized the necessity of using an anesthetic in the first examination of fractures about the elbow-joint. The majority of cases of ankylosis of the elbow following fracture being due to bony displacement or to callus if non-operative measures were not successful in removing these causes, something should be done to put the bones in proper position. In compound fractures, all agreed as to what should be done—enlarge the wound and suture the fragments in position. But it was with simple fracture that he dwelt upon. At first sight cutting into the joint and manipulating the structures about the joint, including the capsule, would result in almost if not absolute fixation. Such had not been his experience; the fear of attacking a joint surgically was largely a relic of pre-asceptic times.

He cited the different fractures occurring in the vicinity of the elbow-joint and illustrated his paper by a series of skiagraphs of cases he had operated upon, one, a supracondyloid fracture of the humerus, where the difficulty was found to be due to both callus and displacement. The arm had been treated at an angle of 145 degrees, the condyles were carried backward while the shaft of the bone was drawn forward. In flexion the coronoid process of the ulna struck upon the mass of callus below the more prominent projection of the shaft, while the ulna rested upon the sharp end of the diaphysis in the complete flexion. This boy had a useless arm. The projecting portion of the diaphysis was chiseled off and a new coronoid fossa was cut out with a curette until complete flexion was possible. The result was remarkably satisfactory. In spite of the extensive dissection necessary to reach the anterior surface of the humerus and the consequent lacerating and bruising of the capsule and synovial membrane, flexion was obtained almost to the full extent. Skiagraphs were shown further illustrating varieties of fractures about the elbow-joint complicated by callus and dislocation upon which he had operated generally with success. He summed up the management of fractures of the elbow in the following words: (1) Examination and reduction under ether. If the latter is impossible, and it is evident that disability will result in consequence, immediate incision and dissection until the fragments can be forced into position and wired or sutured. If, however, this is still impossible, the fragments should be removed. (2) If ankylosis or marked limitation of motion results and does not prove to be due to fibrous bands, operation should be undertaken and everything opposing the proper

movements of the joint should be cut away. He said when he performed his original operation in 1894, he was unable to find any records of previous operations of the kind, but now many The open method of treatment had been advocated much earlier in irreducible dislocations of the elbow and it seemed strange that it was so late in coming into more general use in fractures. In all his cases, twenty-one in number, the posterior incision similar to that made for excision of the joint was employed. This answered well for manipulation of the olecranon fossa of the humerus or the injuries to the condyles. The difficulty of clearing out the coronoid fossa and managing the anterior displacements was greater. He varied the incisions according to the injury. The capsule should be as carefully opened and sutured as the peritoneum. He said one could scarcely be too radical in removing bone; it was better to try for both flexion and extension than to stop short of removal of any obstruction. After removal of bone he flushed the joint with hot normal saline solution, sutured the capsule carefully and closed the wound without drainage. Rest in flexed position for one week, then massage and active motion. Dr. Lloyd also presented two patients upon whom he had operated to further illustrate his paper.

Dr. B. Farquhar Curtis opened the discussion of Dr. Lloyd's paper with the remark that he approached these injuries followed by bad deformity of the elbow-joint with great caution; these operations were among the most difficult of surgical procedures and a great test of the asceptic methods of the operator. He thought suppuration was very apt to occur and if so, particularly if serious, the benefit of the operation was lost. Another point was the impossibility of calculating upon the production of new bone or of checking its formation, the overproduction being almost certain to occur. Again, fracture, particularly in children, was near the epiphyseal line and the surgeon was often confronted with the necessity for removing the epiphysis with the result of checking the growth of the limb. He differed with Dr. Lloyd in that he treated recent fractures of the condyles of the humerus with loss of the carrying point, in the extended position for ten to fourteen days, then flexing the elbow-joint—other cases in the flexed position from the first; massage began within the second or third week in all fractures near the elbow-joint. Dr. A. B. Judson commented upon Dr. Lloyd's use of skiagraphy, saying that he had not seen a more useful application of the X-ray to surgical procedure.

Effect of Flexion of the Spine on Rotation.—Dr. Judson exhibited a stick of sponge-rubber made to represent the spine, with pins in place of the spinous processes. The object was to see whether flexion or extension were able to affect in any way the rotation which accompanies lateral curvature. The model had been photographed (1) in lateral curve combined with flexion and (2) in lateral curve combined with extension, but it was seen that in either case there was no trace of rotation. Further observation and reflection brought to light the fact that the curve in either case was in reality a simple curve. Although produced by a combination of a lateral and an antero-posterior curve, it was in reality a simple curve lying somewhere between the two, the resultant of two forces, but with no more power to affect rotation than any other simple curve however produced. It had been suggested that if flexion could really be considered as causing rotation, its opposite, extension, would be useful in combating rotation. Too much, perhaps, could not be said in favor of forced extension, as in the treatment of Pott's disease. The immediate effect of this would be to transfer the weight from the bodies to the processes, which would be a good thing, as the processes were held near the middle plane and were, therefore, less abnormal in their position than the bodies which in curvature swung away from the middle plane. This freedom of the bodies combined with arrest of lateral motion on the part of the processes was what produced the phenomenon of rotation.

Dr. Charles H. Jaeger demonstrated the Lorenz hip redresseur—a simple and convenient apparatus for the application of bandage to the lower extremity, its chief use being to correct faulty positions of the limb and then to hold the limb in the corrected position while the fixation bandage was applied. Its advantages are (1) dispensing with one or two assistants; (2) retaining limb in position; (3) stronger traction than could be applied by hand and kept up evenly. He presented a patient wearing a Lorenz spica. Attention was called to necessity of carefully modeling the plaster over the iliac crests, also to the padding used—first, a tricot which enveloped leg and abdomen, then a thin layer of ordinary non-absorbent cotton cut in strips four or five inches wide, glued on both sides and applied like a roller bandage.

Dr. Sayre had seen an apparatus similar to the redresseur, devised by Bruns of Tubingen. He thought that of Lorenz superior. Dr. Gibney expressed himself as much pleased with the redresseur.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXIX. NEW YORK, SATURDAY, OCTOBER 5, 1901. NO. 14.

SPECIAL ARTICLE.

THE UNIVERSITY AND BELLEVUE MEDICAL COLLEGE.

THE University and Bellevue Hospital Medical College in New York City is to-day an important force in medical education. It is like a river that has suddenly grown wide and deep enough to bear an ocean fleet, whereas before there were two streams subject to the conditions of drought and flood. In other words it is but three years since the University Medical College was joined by that powerful tributary, the Bellevue Hospital Medical College. To trace the course of these confluent streams that now flow in such a wide educational channel, we must start from two distantly separate sources, and follow their development of medical progress along different lines, up to the recent time of their converging and union.

The University Medical College is the main stream, although perhaps not the more celebrated of the two, for it had its rise nearly a quarter of a century before Bellevue College, in the days when the College of Physicians and Surgeons represented the sole medical center of New York City.

In 1838 a number of eminent practitioners who had at one time or another been prominent in medical institutions decided that in the growing city there was not only room, but need for another medical school, and accordingly broached to the New York University, then called the University of the City of New York, the idea that a medical school be founded in connection with that institution. The idea was accepted with an organized faculty of men whose names have since become famous; but before it became a reality circumstances arose which caused the prospective medical faculty to sever their connections with the New York University, and to offer their embryonic medical school to Columbia College. This step caused some alarm to the College of Physicians and Surgeons, whose influence against the new school led the Trustees of Columbia College to politely decline the budding faculty's offer on the ground that they feared a medical school would be detrimental to the Academic Department. After their rejection by Columbia College it was determined to apply to the Legislature for an act of incorporation.

The County Medical Society and the Trustees of the College of Physicians and Surgeons indorsed the application to the Legislature and all active opposition was removed. While action was thus pending negotiations were again opened with the University which were successful and the following were accepted as the Faculty of the Medical Department:

Professor Valentine Mott, Surgery; Professor Granville S. Pattison, Anatomy; Professor Gunning S. Bedford, Obstetrics and Diseases of Women; Professor John Revere, of Jefferson Medical College, Theory and Practice of Medicine; Professor Paine, Institutes of Medicine and Materia Medica, and Professor John W. Draper, Chemistry.

These six professors purchased the large granite building, known as Stuyvesant Institute, for the College. This building, with the exception of the University and the Astor House, was considered the finest building in the city and was situated on the western side of Broadway opposite Bond Street.

The founding and equipment of the Medical School proved so heavy a burden on the Faculty that they decided to apply to the Legislature for

GRANVILLE SHARP PATTISON, M.D.

pecuniary aid, accordingly Professor Paine appeared before the Legislature during the winter of 1844 with a petition which in spite of opposition obtained a grant of $3,000 a year for five years or longer. By an alteration, however, of the Constitution of the State, affecting all legislative grants, the College enjoyed this gratuity for three years only.

The College continued to be conducted in the Stuyvesant Institute until the year 1851 when the property was sold and a new and specially designed college building was erected on East Fourteenth Street between the Academy of Music and Third Avenue. At the time of its completion it was the best equipped and most commodious medical college building in the country.

The College remained at this location with gradually increasing classes until it was destroyed at the time of the burning of the Academy of

Music in the spring of 1866. The loss was not limited to the building, but many of the records of the institution were destroyed, together with collections in anatomy, chemistry, materia medica, botany, etc. Not only did the University Medical School suffer from the fire, but during the Civil War its fortunes ebbed so low, that its very existence was threatened. From its founda-

GUNNING S. BEDFORD, M.D.

tion it had attracted many students from the South, for a large number of its professors were Southern men, accordingly when the war broke out, and the men from the Southern States ceased to attend, and the Northern students enlisted, the classes were practically deserted. However, it soon regained its prestige and in 1879 one of the largest medical classes ever graduated in America

A. L. LOOMIS, M.D., LL.D.

(204) received diplomas from the Chancellor of the New York University.

After the fire the Faculty took up their quarters in the old New York Hospital which at that time occupied the square bounded by Broadway, Church, Duane and Worth Streets, but were compelled to give it up three years later on account of the sale of the property.

At the earnest solicitation of Professor Henry Draper, the late Cortlandt Palmer was induced to erect a building for the College at 426 East 26th Street, which he leased to the Faculty for a term of years, but this did not accommodate the rapidly increasing classes and as it was deemed impracticable to enlarge it, a new site was bought at 410 East 26th Street, and a building completed in 1874, which like its predecessor on East 14th

WILLIAM DARLING, M.D.

Street, was at the time of its occupation a model building for the uses of the school as medical education was then conducted.

In 1882 the property adjoining the College was purchased and a large dispensary building, with laboratories and class-room, was added to the equipment of the school, and in 1886 the Medical Faculty received a donation of $100,000 for the

JOHN WILLIAM DRAPER, M.D.

erection and equipment of a new laboratory building which, by the request of the donor, was to be known as the Loomis Laboratory.

To Alfred L. Loomis who occupied the Chair of Theory and Practice of Medicine from 1867 until his death in 1895, the College, alumni and medical profession owe a debt of gratitude and the present generation of medical men will always associate the University Medical College with his

name. As a didactic and clinical teacher he was unexcelled, as he had the rare gift of so impressing the student that after leaving the class-room he seldom forgot the points that had been emphasized during the lecture or clinic. He always had a keen interest in the welfare both of students and graduates and the interests of the College were always especially dear to him. It was largely due to his untiring energy in its behalf that the success of the College was so phenomenal.

The students who sat under the teaching of Professor William Darling will always have a vivid recollection of the picture he presented while conducting his lectures and at the same time occupying his hands, when not otherwise employed, with some useful work. As a pure anatomist he probably had no equal in the country. He devoted the greater part of his life to its teaching. His eccentricities were numerous and, although in comfortable circumstances, he practised the most rigid economy, having his rooms in the college building and lived surrounded by anatomical material and anomalies.

JOHN REVERE, M.D.

MARTYN PAINE, M.D.

The name of Draper, which has always been associated with the University as well as with the advance of medical science, was represented by three members of that distinguished family, Dr. John W. Draper, who occupied the chairs of physiology and chemistry, Dr. H. W. Draper who succeeded him in the former 1867, and Dr. J. C. Draper who took the chair of chemistry in 1865.

Among others the famous men that have been connected with the school were: Professor Samuel D. Gross, who occupied the chair of surgery for one session afterward going to the Jefferson Medical College, Professor John T. Darby who came from the University of South Carolina and remained with the College until his death, Professor Dickson who also came from the University of South Carolina and later was professor in Jefferson Medical College, and Professor William H. Van Buren who for a while was professor of anatomy and afterward became professor of surgery in Bellevue Hospital Medical College.

Not only have famous men begun their careers at the University Medical School, but another of New York's well-known schools of medicine owes its origin to the post-graduate course founded by the University in 1875. This was a course given by a "Supplementary Faculty" of professors for the purpose of facilitating the efforts of graduates in medicine who had come to New York to renew professional studies, and who after satisfactorily completing it received certificates. It lasted for seven years only and was then abolished.

The professors who had been interested in it, and who were separate from the Governing Faculty asked to be allowed to grant degrees instead of certificates and they also desired to have a separate system of fees, separate lecture-halls, etc., and to be allowed to share in the general government of the college; but after due consideration by the Governing Faculty it was decided that this proposal would not accord with the policy of the College and it was therefore deemed for the best interests of the institution to accept the resignations which were tendered by the majority of the post-graduate professors who seceded in 1882. The professors who withdrew from the College at this time were the founders of the present Post-Graduate Medical School.

An incident of great interest in the history of the Medical Department of the University is the part of the Faculty in obtaining from the Legislature an act legalizing the study of anatomy, as it was then a State prison offence to dissect any part of the human body for anatomical purposes. Professor Martyn Paine by his persistent and self-sacrificing labor at Albany succeeded in 1854 in having the objectionable law repealed and dissection legalized.

Previous to 1890 a large percentage of the matriculants at the University Medical College and at its sister institution Bellevue Hospital Medical College were from other States in the Union. With the passage of the Medical Law demanding that all those who received the degree from colleges within the State of New York

should obtain a medical students' certificate, issued by the Regents of the State of New York, a marked falling off in attendance was noted. This, together with the continued growing expense of conducting a medical college on account of the extensive Laboratory courses, etc., brought vividly to the attention of the Faculty the need of a closer association with the University proper, as up to this time the running expenses of the College and salaries of the Professors and Instructors were dependent upon the fees of the students; accordingly in the spring of 1897 the Trustees of the College property, most of them members of the Faculty, transferred it unconditionally to the University Corporation. But the most important step was that which was finally taken in 1898 when at the commencement exercises the official announcement was made of the consummation of the consolidation between the University Medical College and the Bellevue Hospital Medical College.

Thus, with the medical school that was cradled in a University was joined that school of medicine that has been the outgrowth of the most practical work of New York City. It was no sentiment of independence or jealousy that gave birth to the Bellevue School of Medicine, but rather the absolute prodigality of clinical material that was going to waste in Bellevue Hospital and that attracted so many students that, finally, in spite of themselves they formed a school.

The earliest reference to public instruction in this hospital that has been found is a short note in the "Medical Repository" for 1804 to the effect that Dr. Valentine Seamen had begun a course of lectures on the obstetric art intended particularly for the education of midwives. But the instruction given in other branches for many years was wholly informal. The physicians who gave their services for charity to the City's sick, walked the wards attended by their private students.

As soon as Bellevue Hospital was placed under the control of a medical board with division into a medical and surgical service, the board, as one of its first acts, made provision for an amphitheater which was formally opened March 2, 1849, by Dr. William H. Van Buren, who performed the operation of lithotomy. Notice was then given that students would be admitted without charge to the clinical lectures on every Friday at one o'clock. These clinics were continued for a little over a year, but during the ensuing five or six years clinics were held occasionally, but with no regularity. This, then, is the beginning of that clinical teaching with which the name of "Bellevue" has since become synonymous.

The desire that had ever actuated the Medical Board from its organization to apply the great clinical advantages in the hospital to the purpose of instruction received a new stimulus in 1857. This was the completion of a building to be used for pathological studies. It was due largely to the energy and zeal of Dr. James R. Wood and it contained a spacious lecture room and museum which is the "Wood Pathological Museum" of Bellevue Hospital.

W. H. VAN BUREN, M.D.

JAMES R. WOOD, M.D.

While this building was in course of erection a committee arranged a plan for clinical instruction, which was announced by Dr. Wood on the opening of the lecture room, October 19, 1857. This marked the beginning of opportunities for and work in autopsy and gross pathology and early left its impress upon the medical profession of the city. On December 18, 1860, at the request of the Board of Commissioners of Public Charities and Corrections, the Medical Board appointed a committee to examine and report upon the various institutions upon Blackwell's Island under the control of the Commissioners with a view to the medical departments of these institutions coming under the care of the Bellevue Board. In their report to the Medical Board this Committee recommended the establishment of a medical college in connection with Bellevue Hospital. The Medical Board approved of the suggestion and a committee was elected to confer with the Commissioners.

The Commissioners approved of the plan and

recognized that not only would the cause of medical education be aided, but the welfare of the sick poor would be greatly benefited by the founding of a medical school in connection with the Hospital.

These schemes rapidly took shape and in

FORDYCE BARKER, M.D.

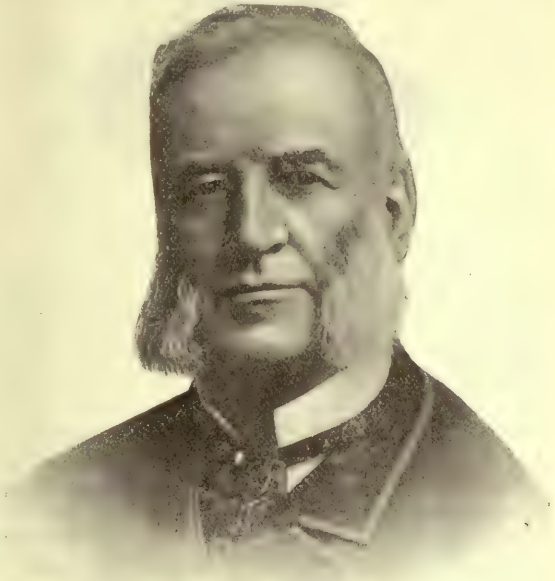
March, 1861, eleven out of the active members of the Medical Board signified their willingness to connect themselves with the proposed college These were Drs. Taylor, Wood, Hamilton, Sayre, Mott, Stephen Smith, Barker, Elliot, McCready, Gouley, and Loomis. The Board of Commissioners were enthusiastic in their endeavors to increase the value of the charitable institutions under their care by making them subserve more completely the cause of medical education and notified the Medical Board that they would allow a college building to be erected upon the hospital grounds. Steps in this direction were accordingly taken. During April, 1861, the following members of the Medical Board were elected to the Faculty of Bellevue Hospital Medical College, which was the title of the new school and chairs were assigned as follows: Principles and Practice of Surgery, Dr. Stephen Smith; Surgery of Bones and Accidents, Dr. Frank H. Hamilton; Operative Surgery and Surgical Pathology, Dr. James R. Wood; Surgical Anatomy, Dr. Alexander B. Mott; Orthopedic Surgery, Dr. Lewis A. Sayre; Obstetrics, Drs. Isaac E. Taylor, Fordyce Barker and George T. Elliot, Jr.; Materia Medica and Therapeutics, Dr. Benj. W. McCready; Principles and Practice of Medicine, Dr. Austin Flint; Anatomy, Dr. John W. S. Gouley; Physiology, Dr. Austin Flint, Jr.; Chemistry and Toxicology, Dr. R. Ogden Doremus.

The first exercises of the College, as such, were short courses given during April and May, 1861, by Professors Wood and Hamilton on points connected with military surgery, a subject which the breaking out of the war rendered particularly important. These lectures were attended by two hundred practitioners and students.

In the meantime the College had been incorporated and placed under the control of a Board of Trustees of which the Commissioners of Public Charities and Corrections were members. During the following summer the first building of the College was erected.

In June, 1861, Dr. Gouley considered that his duty demanded that he remain in the army during the continuance of the war, and he therefore resigned the chair of anatomy and Dr. Timothy Childs was called to fill the vacancy.

Probably the prospectus of the new school because of the war caused a falling off of students in the University School. The first session of the College was opened the following fall and from the beginning the capacity was taxed to the utmost, so that before the first session was finished the necessity for a larger building was felt, and it was proposed to procure ground opposite the entrance to the Hospital and build a new College outside the Hospital grounds. The Commissioners of Public Charities and Corrections, however, were unwilling that the College should go outside the Hospital grounds and proposed to erect a new building and lease it to the College. This proposal was accepted and in May, 1863, the Faculty of the College presented to the Commissioners a complete plan of organization for the Bureau of Medical and Surgical Relief for the Out-Door Poor. During the autumn of 1865 the Commissioners erected a large building within the Hospital grounds so arranged as to serve the



AUSTIN FLINT, M.D.

purpose of College and Out-Door Poor. The lower floor was divided to answer the purpose of Dispensary and the upper part was leased to the Faculty for the use of the Medical College. This arrangement allowed of the use of clinical material not only from the wards of the Hospital,

but also from the Dispensary and enabled the Faculty of the College to develop the clinical teaching on the broad lines that was always one of its peculiar characteristics.

No change occurred in the personnel of the Faculty until the death of Professor Childs in September, 1865, at which time Professor Stephen Smith was appointed to the chair of anatomy, and the principles of practice of surgery which had formerly been under Professor Smith's charge were assigned to Professor Hamilton in addition to his other duties.

In 1866 the Faculty recognized the necessity of furnishing the students with instruction upon the special branches in greater detail than could be well considered in the course given by the professors of the seven chairs already demanded by the Charter of the School, and therefore in the spring of this year Dr. Henry D. Noyes, formerly demonstrator of anatomy, who had been holding clinics at the New York Eye and Ear Infirmary was made professor of ophthalmology and in the summer course, which was this year established,

I. E. TAYLOR, M.D.

VALENTINE MOTT, M.D.

Dr. F. J. Bumsted was appointed professor of syphilology, Dr. Foster Smith, lecturer on diseases of the skin, and Dr. J. Lewis Smith, lecturer on morbid anatomy. Dr. William H. Van Buren was made professor of diseases of the genito-urinary system. In 1867 a chair of diseases of the mind and nervous system was established and Dr. William A. Hammond was elected. In 1871 dermatology under the charge of Professor E. L. Keyes and pathological anatomy under Professor Edward G. Janeway were introduced into the curriculum of the regular session. During this same year a medical clinic was established under the direction of Professor William T. Lusk, who had been elected a member of the Faculty to fill the vacancy caused by the death of Professor Elliot.

The members of the corps of professors who organized the College were far from being inexperienced. Many of them had already held chairs of their respective branches in other institutions, and others had been clinical lecturers in the adjoining Hospital and elsewhere. They were men thoroughly able and accustomed to teach the subjects assigned them. They were men in the prime of life; Taylor was 49, Flint 48, Wood and Hamilton 47, Barker 43 and Van Buren and Sayre 41. As they grew the school grew in reputation with them and by the character of their work in the wards and their zeal in teaching, they were indeed most influential in spreading the fame of Bellevue Hospital as a great center for clinical instruction, so that their names became a guarantee throughout the land of the value of the instruction given at Bellevue Hospital. A word of reminiscence concerning these men cannot fail to recall the personalities that made the school famous.

Dr. James R. Wood was a comparatively small man physically, mentally, however, of more than usual proportion. A man of earnest action and loyal attachments, not only to his friends, but to every duty belonging to his station and line of action that commanded his attention. He was scrupulously neat in his attire on all occasions and when visiting the hospital wards wore a boutonnière. His interest in Bellevue Hospital and also in the school bearing a somewhat similar name was indefatigable and decided in its outcome. Rapidity of action characterized his operative procedures and clearness of judgment and wisdom his consultations.

Dr. Isaac E. Taylor was a man of generous impulses and of almost feminine instincts. He was ever ready to listen to the requirements of need and prompt to extend abundant assistance. He was keenly interested in the professional honor of those engaged in medical calling, and severe and rapid in his condemnation of those who by word or action brought censure or reproach upon the profession of medicine.

Dr. Hamilton was courteous in every association to his fellow-men, professionally and otherwise. As a medical teacher, he had few equals and the uniform consideration shown by him to every member of the class promptly established a mutually strong, respectful attachment between

them. His concise and scholarly expressions, illustrative of the subjects under consideration, characterized him as a teacher and a debator upon surgical topics.

Dr. Mott was an operating surgeon of high order whose rapidity of action and success in this line bespoke the instruction of his famous father. His lessons in surgical anatomy were practical and contributed largely, indeed, to make the operative labors of those who were privileged to listen to his instruction lighter and fruitful of good results.

Dr. McCready's instructions in materia medica and therapeutics were emphasized not infrequently by illustrations so characteristic of the genial and humorous nature of the lecturer as to make it impossible for one to forget the points he wished to impress. He was a gentleman of more than usual professional and literary attainment and one always welcome in circles characterized by genial relations and scientific attainments.

Dr. Elliot was polished in his manners, appearance and education to the fullest extent. He was courteous to all who indicated by their attention their interest in his efforts to instruct them and prompt to rebuke unwarranted liberties and inattentions that not unfrequently characterize the lecture-room and hospital wards. He seemed desirous that all those with whom he came in contact should have in view the same high standard of thought and action that characterized his intercourse with the unfortunate and suffering in the professional walks of life. His death was an irreparable loss to the school with which he was connected and to the medical profession of which he was a highly respected and useful member.

It is owing to the excellent executive ability of Dr. Lewis Albert Sayre that the school made such strides in these early days. Dr. Sayre graduated from the College of Physicians and Surgeons, New York, and was appointed a prosecutor to the professor of surgery at this institution. In 1853 he was made surgeon to Bellevue Hospital. He soon became professor of orthopedic surgery and fractures and luxations in the new school.

It was due to Dr. Sayre in large part that New York has developed such an excellent sanitary system, for he served as resident physician of the City of New York. His quarantine provisions were well in the foreguard of modern scientific progress and served as efficient barriers to the entrance of several severe epidemics to New York City.

When in 1882 the death of Professor James R. Wood occurred followed soon after (1883) by the death of Professor Van Buren, it was not the College alone, but the Hospital and the medical profession at large that suffered also. Flint and Hamilton were the next to follow in 1886. Seldom is it that any college is called upon to sustain such grievous losses in its teaching body and many are the men throughout this country who revere the memories of these masters of medicine and count themselves fortunate that they have these names added to their diplomas.

The year 1889 marked the death of President Taylor and of Professor Mott. Professor Taylor had been President since the foundation of the college, but had not been actively teaching, having been emeritus professor of obstetrics and diseases of women and children since 1867.

Dr. E. G. Janeway was promoted to the full professorship in medicine on the death of Professor Flint. Professor Janeway had joined the school in 1872, coming from the Medical Department of the New York University where he had been professor of physiological and pathological anatomy. Professor Janeway resigned the chair of medicine in 1892 and was succeeded by Professor A. Alexander Smith, '71, who had for thirteen years been professor of the subjects of materia medica and therapeutics.

The chair of anatomy made vacant by the decease of Professor Alpheus B. Crosby had been held by Professor Joseph D. Bryant, '68, since 1878 when in 1883, after the death of Professor Van Buren, he was appointed clinical professor of surgery and associate professor of orthopedic surgery, while still retaining the chair of anatomy. Dr. F. S. Dennis was made professor of the principles and practice of surgery.

Another great loss to the College during this period was that in 1884 when Dr. William H. Welch, Professor of Pathological Anatomy, resigned to take the professorship of pathological anatomy in Johns Hopkins University.

In 1884 the College received a donation of fifty-thousand dollars from a member of the Board of Trustees, this sum to be devoted to the erection of a suitable building for laboratories and the purchase of apparatus. Members of the Board of Trustees and other friends of the College provided a lot of land on East 26th Street, fifty by one hundred feet, a short distance from the hospital and the new building was erected here. This building was opened for work in 1885 and was devoted mainly to laboratory work in physiology, pathology, therapeutics and other departments of medicine. It was with the view of fostering original research in the newer science of bacteriology and of disseminating a practical knowledge of what had already been developed that Mr. Carnegie made his generous gift to the College. This College was, therefore, one of the earliest beneficiaries of Mr. Carnegie's gifts.

It is this fine equipment together with the record of the life work of brilliant men that the Bellevue Medical School has brought to the University Medical School in the act of consolidation.

The teaching forces of the two colleges, which now numbers 120; the completion of the new college building on 26th Street; the thorough equipment of the laboratories, the opening of the new clinic, where over 40,000 patients are treated annually, together with the clinical material available in the Hospitals under the Department of Charities and also the private hospitals of the City, offers to the medical student and graduate facilities for a thorough medical education and practical training.

ORIGINAL ARTICLES.

ACUTE RHEUMATISM.

BY WM. WATT KERR, M.D.,
OF SAN FRANCISCO;
PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF CALIFORNIA.

IN INTRODUCING the subject of acute rheumatism, I shall first present as illustrations of the disease two patients from the wards. The important points in the histories are included in the following abstracts.

Case I.—Male, age thirty-three years, rigger by occupation, and served in the army for two years during the recent war. The family history is good, there being no rheumatism in the family so far as he is aware. Had measles, mumps and diphtheria when a child; there is no specific history nor former attacks of rheumatism, but he drinks to excess occasionally. More than a year ago he dropped from a height of fifteen feet and landed in an upright position upon a stone floor; no bones were broken, but he was unable to walk for nearly four months on account of pain in the ankles.

His present illness began a few days before admission to hospital with dull pain in the left knee, which in forty-eight hours became very intense and was accompanied by swelling and redness; the pain extended to the left ankle, then to the right ankle, and there was marked pain and tenderness along the left sciatic nerve, but no loss of power. At the same time he had a smothering sensation in the left chest, and on examination a well-marked systolic mitral murmur was discovered; in addition to this there was pain as well as other signs of pleurisy on the same side. The degree of fever was moderate.

The patient was given twenty grains of salicylate of soda every two hours, and a small blister was applied over the precordia, with the result that, within twenty-four hours, the pain had almost disappeared from the joints, the cardiac murmur was much less distinct, and at the end of four days the patient was free from pain, while, so far as physical signs were concerned, the heart had become perfectly normal. Five weeks later he was transferred to the surgical wards on account of a slight rectal trouble from which he had suffered for some years, and on his return to this ward I found him showing signs of peripheral neuritis in both lower limbs, and from dropsy in the lower limbs. Examination showed the area of cardiac dulness increased, together with a weakened pulse, which suggested the existence of myocardial changes.

Case II.—Male, aged thirty-one years, milker. The only important points in his personal and family history are that his father suffers from rheumatism and that he himself has had three previous attacks. Prior to his present sickness, he suffered from slight pains in his feet, but the acute attack began with pain, swelling and tenderness in the left knee, which two days later shifted to the left hip, then to the right knee, and afterward to the right foot; then the left shoulder and left wrist became involved in the order mentioned. On admission, a faint pericardial friction could be heard, which for a time became more pronounced, and did not finally disappear until nearly four weeks after admission. He suffered from profuse perspiration and fever, with an evening exacerbation, which on one occasion rose to 103.2° F.

The treatment was similar to that adopted in the former case and yielded as speedy results, but there have been three relapses due to the fact that it was absolutely impossible to keep the patient at rest after the pain had disappeared from his limbs. One of these relapses was associated with endocarditis.

A comparison of the two cases shows points of similarity and difference. Both patients had fever, sweats, and endocarditis; in one, the joint symptoms were well marked; in the other, they were of medium severity, but this patient suffered from sciatica.

Such are the symptoms of two average types of rheumatism. How far can they be explained by the pathology of the disease? Unfortunately, our knowledge of this subject is still very deficient, but for the last fifteen years the belief has been increasing that rheumatism is an infectious disease due to the introduction of a microbe; indeed, the nervous, the humeral, and neuro-humeral theories have all proven so unsatisfactory that they may be omitted from the present discussion.

It has been suggested that the disease is simply an attenuated pyemic infection, but, while the symptoms resemble those of pyemia, close observation shows sufficient difference to warrant the hypothesis of distinct poisons. The tendency of pyemic infections toward suppuration affords a marked contrast to the extreme rarity of suppurative changes in tissues which have been affected by rheumatism. Another theory, based chiefly upon studies of malignant endocarditis, ascribes rheumatism to a mixed infection, but no satisfactory bacteriological support has been found for this hypothesis. The subject is still further complicated by the fact that at least three micro-organisms have been discovered, each of which has some claim to be regarded as a factor in the production of the disease.

Recently Poynton and Paine have pubished the results of some observations and experiments regarding a diplococcus, which is probably identical with that described by Triboulet in 1897. In twelve consecutive cases of rheumatic fever, these gentlemen have isolated a diplococcus which, when injected into the veins of rabbits, has produced polyarthritis, pericarditis, valvulitis, pleurisy, pneumonia, chorea and nodules; all the lesions were non-suppurative in character. This micro-organism has been obtained from the blood, urine, and tonsils of the patient suffering from rheumatic fever; while after death it has also been discovered in the peri-

cardium, cardiac valves, pleural and pericardial exudations, and rheumatic nodules. A study of its life history in the human and animal tissues leads to the belief that it is destroyed at the sites of the local lesions, although there frequently remains some damage to the tissues in which the diplococci were localized. These investigators very justly claim that they have discovered a cause of rheumatic fever, but that they are not yet in the position to demonstrate that their diplococcus is the only cause.

Rheumatism is a general disease in which there is a tendency toward inflammation of the serous and synovial membranes, and consequently the symptoms must be sought not only in the joints, but in every part of the body where serous or synovial membranes exist. Apart from the bacteriological testimony, there is an abundance of clinical evidence to warrant the conclusion that the disease is general and not local, and a recognition of this is necessary to enable a discrimination between this malady and the numerous painful affections of the muscles and joints which for so many years have been described as "rheumatic."

The rheumatic attack may occur suddenly, but more frequently there is malaise for two or three days as in both of these cases, and then the pyrexia and other symptoms of the disease appear. From charts of each case, it is evident that there is not anything typical in the fever of rheumatism; generally it is, as in Case II., of moderate severity, about 102° or 103° F., with the maximum temperature in the evening, but it may be absent as in Case I., where the temperature never rose above 99.2° F., until after the patient had been in the hospital for five days, when it reached 101.8° F., but returned to normal within four days. The statement that the fever varies with the number of joints affected is incorrect and misleading. It is by no means uncommon, especially in children, to meet with very slight and transient joint symptoms, but with high fever and frequently inflammation of some other membrane, such as the endocardium or pleura, and I have seen two cases of fatal hyperpyrexia in which the pain in the articulations had almost disappeared, in the one case for more than forty-eight hours, and in the other for nearly thirty-six hours, before the pyrexia began to increase. It is quite true that in the majority of cases in which many joints are involved the fever is also well marked, but this does not demonstrate any causal relation between the inflamed joints and the degree of fever; it is simply a coincidence due to the fact that the pyrexia and inflammation of the synovial membranes are due to a common cause.

In all infective diseases the more intense the infection the more marked do we expect to find all the symptoms, unless the toxin be sufficiently powerful to kill rapidly by an overwhelming influence on the nerve-centers; consequently, when we have a severe infection with rheumatic poison we expect high fever with well-marked inflammation of the serous and synovial membranes, and therefore conspicuous involvement of joints; but should the infection be mild, or become so, we would expect a corresponding diminution in the intensity of the symptoms. The excuse for speaking so forcibly upon this topic is the knowledge that some of you have not been engaged in the study of medicine long enough to divest yourselves of the popular belief that rheumatism is only an inflammation of the joints with visceral complications, and that some of the statements in text-books are capable of misinterpretation and consequent production of confused ideas, while a realization that all tissue changes are simply local manifestations is absolutely necessary to a proper conception of the disease.

Hyperpyrexia occurs more frequently in rheumatism than in any other disease, and it is one of the accidents that the attendant must be instructed to watch for even in the mildest cases; no disease so emphatically demands the regular use of the clinical thermometer. We have no positive indications of the approach of this misfortune, as it may take place where the local symptoms never have been severe, or the disturbance of the central nervous system associated with the rapidly rising temperature may blunt the sensorium so that the patient is less sensitive to pain. On the other hand, when the fever persistently remains in the vicinity of 103° F., and is not associated with any marked disturbance of serous or synovial membranes, or indications of pneumonia, we may feel particularly anxious and be ready to adopt active measures for its treatment.

Sweating is a symptom which was only well marked in one of the patients, but it is present in all cases of rheumatism to a greater or less degree; in some amounting to merely a moist condition of the skin, while in others the bedclothes become so saturated as to necessitate their frequent renewal. In many of the febrile diseases, sweating is associated with the advent of defervescence or the elimination of noxious substances from the system, but this is not the case in rheumatism; the excessive activity of the sweat-glands appears to be part of the disease itself and it is not due to any effort of Nature to counteract the morbid process. The peculiar sour smell of rheumatic perspiration is very characteristic and led to the idea that lactic acid, or some other acid, was being eliminated; but test papers applied to the surface of the body show that the reaction is by no means constant, being acid at one time and at others neutral or even alkaline; furthermore, the reaction may vary on different parts of the body. These facts would suggest that the sour odor and varying reaction are due to secondary changes taking place in the sweat constituents after secretion. This sweating is frequently accompanied by the formation of sudamina and miliaria.

In a large number of text-books the joint affections alone are regarded as local symptoms of rheumatism, while the cardiac, lung and pleur-

itic changes are described as complications. It is a very unfortunate arrangement and tends to obscure the real character of the disease, because, as we have seen from our preliminary review of the pathology, the inflammation of the endocardium, pleura and other serous membranes, is just as much a part of rheumatism as is the inflammation of the synovial membrane covering the joints. This is not a quibble in nomenclature, but the recognition of a fact that is of importance in treatment and prevents the tendency to gauge the progress of a case by the condition of the joints, which, although more conspicuous, are of secondary importance when compared with danger to life or possibility of permanent ill health that may follow even a slight lesion of the thoracic viscera.

The three characteristic features of arthritis as it is seen in cases of acute rheumatism are well illustrated in Case II. The larger joints are chiefly affected. The disease is polyarticular. The arthritis is metastatic.

The appearance of the affected joints varies. Sometimes there is not any visible alteration, but simply pain which is increased upon the slightest attempt at movement, while in other cases there is marked swelling, tension, and redness. The large joints are much more liable to be attacked than those of smaller size, and more than one is involved at the same time, except when the type has become subacute, and then it may happen that only one articulation is affected. Another peculiarity is the metastatic character of the pain, the inflammation suddenly disappearing from one joint to appear in another, very often in the corresponding part of the opposite limb, and then it may reappear in the original site. This clinical feature is possibly the strongest evidence of the general nature of the disease and finds its explanation in the statement already made that the micro-organism is destroyed at the site of the local lesion.

The coexistence of acute rheumatism and sciatica is not often so well marked as we found it in Case I. Probably this nerve trouble was simply a perineuritis, although rheumatism is capable of producing a true neuritis.

The physical signs indicating involvement of the thoracic viscera do not need any special description beyond calling attention to the fact that they may be as evanescent as those met with in the joints. Thus, in Case I., the cardiac murmurs lasted for a few hours only, and in Case II., the pleuritic attack was equally short. But although signs of endocarditis are often of brief duration it not infrequently happens that during convalescence, or even subsequent to that time, the signs of permanent valvular lesion may appear, and this happens because the rheumatic poison originates changes in the valve which lead to sclerosis and shortening of the segments. As the aortic valve segments are devoid of blood-vessels, it has been suggested that the micro-organism enters this portion of the endocardium through the epithelial cells lining the membrane. It has been demonstrated that the endothelial cells lining the vascular system have phagocytic properties, and hence it is not at all improbable that micro-organisms enter the tissues in this manner, and that in the exercise of their phagocytic functions the cells themselves are injured.

The injury to the myocardium is not easily estimated during the rheumatic attack, as there are so many conditions at this time, apart from myocarditis, to influence the pulse. Case I. has been convalescing for nearly eight weeks, but has been detained in hospital on account of some slight rectal trouble requiring surgical treatment; during the last fortnight he has developed edema of the feet and lower limbs, with diminished pulse force, although no signs of valvular lesion can be detected and the urine is normal. Evidently the myocardium had become weakened so that when the patient resumed active habits it yielded under the strain.

Remember also that the heart may become involved, especially in children, so insidiously as not to give rise to any special symptoms sufficient to attract the attention of the physician, and hence a constant watch must be kept for the appearance of the physical signs indicative of each lesion; the heart should be examined regularly without waiting until the patient complains of dyspnea, faintness, or pericardial pain.

Sore throat, which is a very common symptom, was absent in both of these cases. So frequently is tonsillitis found among the early signs of rheumatism that the tonsils are regarded by many as the great port of entrance of the rheumatic poison into the body.

In the treatment of rheumatism, rest in bed is an essential factor, and should be maintained for at least ten days after the temperature has become normal and all other symptoms of the disease have disappeared. Freedom from pain in the joints must not be taken as the indication for allowing any indulgence to the patient, because cardiac changes may arise after the joints have recovered; furthermore, myocardial changes may exist with very few symptoms until the muscle yields under imposed strain, and therefore the patient should be kept at rest so that both myocardium and endocardium may have ample opportunity to recover from any injury to their structure.

Sodium salicylate is the remedy most frequently used in the treatment of rheumatism. It should be given in doses of twenty grains every two hours until the fever is reduced and the acute articular pain subsides, after this the intervals between the doses may be increased to four or six hours, and continued in this way for at least four weeks. If the drug be discontinued before this time, the patient is almost certain to suffer from a return of the symptoms, and hence it has been said that acute rheumatism, like other fevers, is a self-limiting disease and that salicylates do not shorten its duration, but merely prevent its injurious effects upon the tissues. The manner in which salicylates act is a matter

of much discussion and must remain so until we have a more perfect knowledge of the pathology of the disease. Clinical evidence appears to encourage the idea that the benefit is obtained from the destruction of toxins, but the fact that the malady recurs unless the remedy is continued for a length of time does not prove the absence of a direct effect upon the micro-organism, because it is a well-known fact that quinine, when properly administered, destroys the parasite of malaria fever, nevertheless if it is not continued in smaller doses for two or three weeks after the plasmodia have disappeared from the blood the chance of relapse is as great as in rheumatism when the salicylates are prematurely discontiued. The solution of the problem awaits a more perfect knowledge of the micro-organism.

The salicylates may distress the stomach, depress the heart, cause delirium or other nervous disturbance, produce albuminuria, or give rise to a variety of skin eruptions. The gastric trouble is often due to the sweetish taste of the drug which may be obviated by the addition of some bitter preparation, such as gentian, to the solution. The cardiac depression may be prevented by the simultaneous use of stimulants, and the nervous disturbance alleviated by the free administration of bromides; yet it sometimes happens that the drug must be discontinued for some of the above reasons, and in the case of albuminuria its temporary or permanent interruption is imperatively demanded. Salicin or salol may be substituted for salicylates except when there is renal disturbance. In addition to the salicylates, an alkali, such as the citrate of potash in twenty-grain doses, should be given so as to maintain the alkalinity of the blood, because clinical statistics show that in cases thus treated there is less tendency to fibrinous deposits upon the valves. Cardiac complications are often cut short by the application of small blisters over the precordia. Of course under such circumstances there is the most urgent necessity for insisting upon absolute rest. This method of counterirritation is not only recommended for the cure of cardiac lesions, but its adoption is advised as a preventive measure in all cases of acute rheumatism. The tepid bath, 70° to 75° F., is the only reliable treatment for hyperpyrexia, and it must be carried out with the precautions already discussed when talking of the bath treatment in other febrile diseases. It is not advisable to do much for the joints beyond keeping them warm and rolled up in anodyne fomentations; blistering and other forms of counterirritation are more useful in the subacute types where the pain is more liable to become limited to one joint.

At first the food should consist chiefly of milk, but, as the symptoms abate, broths, farinaceous substances and white fish may be gradually added to the dietary. During convalescence there generally is a condition of anemia which is best treated by some form of iron such as Blaud's pills.

ANESTHESIA AND ANALGESIA. A STUDY OF DRUG ACTION AND MODERN METHODS.[1]

BY WILLIAM SEAGROVE MAGILL, A.M., M.D.,
OF NEW YORK;
FELLOW OF THE AMERICAN ACADEMY OF MEDICINE; MEMBER OF THE AMERICAN MEDICAL ASSOCIATION AND OF THE MEDICAL SOCIETY OF THE STATE OF WEST VIRGINIA.

Half a century ago there was little need of differentiating analgesia from the general term of "anesthesia," alone in use at that time, for medical science then stood so near the threshold of modern progress over which ether had stepped that its rival, chloroform, was scarcely known by name. The vast field for the application of anesthesia was hardly realized, nor was there any conception of the possible number of the anesthetic agents now in use, nor the variety of action or methods at present distinguishable for ether or chloroform alone.

The production of anesthesia by drug action has developed so great a variety of methods and agents that a study of the subject in general requires a classification.

By defining anesthesia as a more or less prolonged suspension of central perceptions of an impression transmitted through the usual or special sense channels (unconsciousness), we eliminate from consideration as anesthetics such agents as may be used to paralyze the sense organs themselves and thus make impossible the generation of a sense (peripheric) impulse. A special condition of the latter class of agents might require that by purely physical means should be produced the paralysis of the peripheric sense organ, such as is due to the mechanical congelation of the local tissues. In this class belong the so-called local anesthetics, of which the ether spray was the pioneer and the present methyl or ethyl chloride tubes are the more modern developments. The action in all of them is the same—an evaporation cold which arrests the functional life of the affected tissue cells, *i.e.*, their congelation.

None of the chemical compounds of this physical class have any other action that is to be considered as a property of the local anesthesia thus engendered. There are others of the so-called local anesthetics which possess veritable pharmacological properties, extra- and intracellular in their action. Of these, the salts of cocaine, whether in topical application or by infiltration, offer the most typical examples, preventing sense perception by suspension of the peripheric cell vitality, resulting from the temporary vascular constriction, the pharmacological peculiarity of this drug. In this case only the local anesthestic effect is to be considered and alone is desired. The symptoms caused by the introduction of cocaine into the general system are by no means those of anesthesia. In its action by vascular constriction this agent becomes typical of the extracellular division of its class. Pericellular would be a more exact designation term, referring thus to

[1] Read at the thirty-fourth Annual Meeting of the Medical Society of the State of West Virginia, Grafton, W. Va.

the pericellular vascular system, the constriction of which suspends intracellular diffusion and, as a consequence, all vital functions of each affected cell.

A bastard type of such anesthesia, but this time intracellular, in so far as it depends upon the destruction of the cells themselves, is the loss of sensibility of tissue that is characteristic of the more or less caustic antiseptics—the phenol group—and those nitrogen-containing molecules so invariably alkaloidal, from the simple hydrogen cyanide though the hydrogen, carbon, nitrogen amines and alkaloids, up to the oxygen-containing complex molecules of alkaloids, such as aconite or atropine, in all of which the contained nitrogen marks for destruction one or more of the cellular elements of the tissue, and, on such intracellular disruption, conditions the non-transmission of a sense impression.

To consider the foregoing agents as in any sense productive of anesthesia would depart widely from the general definition of that state which, understood in its original intent, requires a general unconsciousness. In all of these agents of local anesthesia mentioned, no general unconsciousness is understood nor permitted to exist. Only the limited locality, submitted to the influence of the agent is allowed to undergo a greater or less alteration of normal sensibility. And not even for the locality affected is there of necessity a complete inaptitude for sense impression. In many cases it is easy to demonstrate that the muscular sense remains, also the perception of cutaneous or mucous contact, and frequently even the power of distinguishing degrees of heat or cold persists indefinitely, with little impaired accuracy, when cocaine infiltration is used.

By pushing to an ultimate analysis the majority of cases for which anesthesia is demanded it will be found that no condition of unconsciousness is either wanted or necessary; not even a localized tissue anesthesia is requisite. All that is usually demanded of an anesthesia, the object of the use of such an agent, is the suppression of pain, only one of the many impressions which sensory nerves convey to the brain.

In most surgical cases, what does it matter if there be consciousness of touch, of heat or of other sense impression, provided that there be no knowledge of existing pain?

The inability to receive a pain-impression constitutes the state of organism defined as analgesia, a term which applies to any painless condition where the remaining sensibilities of the organism are, to all intents and purposes of drug administration, to be considered normal.

In contradistinction to anesthesia we may say that analgesia is a necessary element of the former, but the latter term is only applied to a condition in which no trace of the former is essential or desirable.

For the reason, then, that the so-called local anesthetics never induce a general unconsciousness of the organism to its surroundings, and that the most typical of the group is most decidedly analgesic and not anesthetic at all, let us pass them without further comment than the preceding notes, remarking their generic name of local to distinguish sharply the fact that the entire group—with an exception to be taken up later—are to be thus used as they are rigidly excluded from any general action upon the organism.

Their exclusion from any general action accords to this group, however, a much valued factor of safety, *i.e.*, the absence of dangerous reaction of the general system which assumes a most threatening rôle when real anesthesia is considered. For by definition this last condition alone is resultant of a general drug action upon the entire organism, that which is invariably to be considered as a general intoxication. To produce, then, a general intoxication of the body, prevent all consciousness, but have untouched the vital reflexes of organic life, rapid in induction and in recovery, and affecting to the least possible degree the tissue life and function outside of the desired period of suspended sensibilities, would be the proper idea of anesthesia.

For the means of producing such conditions in ideal perfection, the search is never ending.

First in the order of discovery and still foremost in popular use are nitrous oxide and ether. Equaling, if not more efficacious, although decried as more dangerous, comes their tremendous rival, chloroform, and more recently, exactly as the latter agent concentrates the attack for advantage in a comparison to ether, for the reason that both are eligible for choice for prolonged action of the drug; the nitrous oxide, which (except by special provision) is restricted to a short effect, is as seriously rivaled by the growing claims to a predominant place for ethyl bromide.

There is scarcely any medical journal which does not devote some portion of its space to a report of the struggle for supremacy of the giants of anesthesia—ether and chloroform—or of its skirmishers, the quick-acting agents of short narcosis—nitrous oxide and ethyl bromide.

The dissemination of modern science and its methods of investigation is now so extensive that a body of medical men when investigating the claims of superior adaptability of one or the other of these agents, no longer contents itself nor even considers as of scientific value the relation of individual habits and preferences. The falsehood of statistics is widely admitted and more widely felt when applied to our own experiences. Whatever value experience meetings may have in other fields, the increasing precision of the medical sciences has already attained the level which demands that the full bearing of the fundamental and scientifically controlled facts of the matter at issue be shown before that any experience testimony is acceptable for a solution of the problem of the relative desirability of anesthetic agents.

The object of this paper is to state briefly the usual physiological action of some anesthetics competing for popular favor, and then to point out possible deductions and therapeutical conclusions.

The property of tissue intoxication rapidly producing anesthesia with a minimum of organic shock or reaction is possessed by the simple radicals of the first open chain of hydrocarbons, the saturated series. Taking the first radical of this series, methyl, CH_3—and the second, ethyl—CH_3, CH_2—as types of reference, with the preliminary statement that the property of anesthesia is by no means limited to them but belongs equally to the radicals of this and other open hydrocarbon chains (the unsaturated chain-series, we find by biological experiment to determine relative toxicities (toxic coefficients) that these are least for the simplest saturated carbon radical methyl (CH_3).

The toxicity increases in direct ratio to the concentration of carbon in the radical, as does also the rapidity with which anesthesia can be induced, provided for the latter event that the method of administration be such that the dose-time relation can be maintained unchanging throughout the experimental series. That is to say, in case of administration by inhalation, that there be no marked difference in vapor tension of the successive drugs of the series compared.

The increase of toxicity directly with the concentration of carbon in the radical is nicely demonstrated, together with the increased rapidity of action in the use of acetylene gas C_2H_2. With this agent the anesthesia is induced with great rapidity of action, the passage to the unconscious state being almost instantaneous, but the great excess of relative carbon in the radical gives such a factor of toxicity to the compound that a dose sufficient to produce any pronounced degree or extent of anesthesia is invariably fatal to the life of the organism.

The introduction of oxygen to the hydro-carbon molecule, the formation of an ether, for example, CH_3, CH_2—O-CH_2, CH_3, ethyl ether, apparently renders the anesthetic no more toxic, but slower to induce and so modified that a complete unconscious condition is only to be obtained after a more prolonged and violent stage of cerebral excitement, than is usual where hydro-carbon alone or their radicals combined with the halogens chlorine, bromine, or iodine are used.

The compound formed by any halogen with the organic radical shows greatly increased toxicity and this toxic factor multiplies directly with the number of elements of the halogen introduced into the molecule and likewise directly with the relative density or weight of the halogen in question. Thus the chloride of methyl, CH_3 Cl, is far more toxic than its radical CH_3, or the higher radical ethyl, CH_3, CH_2. In return it is of greatly increased anesthetic energy, a smaller amount of the agent being required to effect unconsciouness and maintaing this for a longer period.

In the same way, the further addition of the molecule forming the bichloride of methyl, CH_2, Cl_2, develops a still greater toxicity as well as energy and the further chlorination of this compound, making chloroform, the tri-chloride of methyl, CH Cl_3, represents the maximum chlorine saturation of the radical and by the same formulation shows the physiological toxicity and anesthetic power of this drug surpassing any of the simpler hydro-carbons, their radicals or oxides (ethers).

By reason of the hyperchlorination of its molecule, chloroform is justly proclaimed more toxic than its rival, but an offset compensation is constituted by its correspondingly increased anesthetic energy. In other words, a much smaller amount of chloroform than of ether, or the lower methyl chlorides would be fatal. On the other hand it is evident that by reason of the increased anesthetic energy of the first article, no such quantity of it is required for the desired effect as would have to be employed for the like effect when the other anesthetics, above enumerated, would be used.

Whether the relatively small dose of chloroform be more, less, or equally toxic to the organism when compared with the larger doses of ether or similar agent that must be employed for an equal physiological response is the precise question to determine the rivalry of these anesthetics and within these limits alone is there field for discussion.

To continue our general laws of toxicity we repeat that this factor is increased directly as the weight of the halogen combined with the radical. That is to say, the substitution of bromine instead of chlorine, in equal numbers of atoms, determines a greater toxicity for the resultant bromide. The elements of the halogen family, of atomic weight heavier than bromine so greatly increase the toxicity of the molecule as to render such compounds dangerous in doses too minute to induce any symptoms of anesthesia.

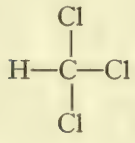
The change of molecule containing chlorine to the similar bromine substitution product by no means increases the toxicity to the degree that the introduction of a second like halogen atom to the radical effects. This means that a mono-bromide is in any case less toxic than the bichloride of the same radical—the administration of either kept below the point of tissue saturation.

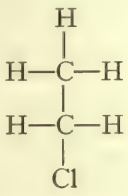
In confirmation of the above we observe that whereas chloroform, CH Cl_3, is safe for internal administration even in doses to the point of producing a marked effect of general anesthesia; almost the same amount of bromoform, CH Br_3, is permissible; but when the additional toxic factor of concentrating the carbon in the radical is added to that of the halogen combination the danger line is soon reached. For example the chloride of ethyl, CH_3, CH_2 Cl, is a comparatively safe and valuable anesthetic, the ethyl bromide, CH_3 CH_2 Br, is also harmless to the point of induced anesthesia, but must here be stopped to avoid the administration of a quantity which by reason of the increased toxicity of the molecule soon threatens the vitality of the tissues, the penalty of their saturation by this drug.

The difference in the toxicity of the chlorine and the bromine molecule is here most strikingly shown.

Notice that the mono-bromide of ethyl, CH_3, CH_2 Br, is harmless for a short administration, but must not be continued, by reason of the accumulating dose rapidly carrying its action across the line of safety. On the other hand the mono-chloride of ethyl, CH_3, CH_2 Cl, can be used for a relatively prolonged anesthesia and by many investigators, with strong physiological experiments to back them, the fact is insisted upon that it is essentially a far safer agent of anesthesia than chloroform, the tri-chloride of the safer radical methyl.

Place the chemical formulæ in antiposition and judge for yourselves.





Exception taken for the molecular differences and consequent wide variation of toxicity, the two rival anesthetics, ether and chloroform, possess very similar physiological properties. Both are best and practically exclusively administered by inhalation in order, by reason of the extended area of absorption surface offered by the areolar tissue, to secure the rapid saturation of the blood to exactly the requisite degree at the same time maintaining the minute control of dose of the inhaled vapor which is essential where such active agents of intoxication are employed to bring about a necessary general reaction, the least over-effect or prolongation of which would be dangerous if not fatal to the life of the organism.

The wide limits of quantity within which ether can be safely used render its method of exhibition of relatively small importance and the only requisite of apparatus insisted upon is an arrangement for sufficient aeration of the inhaled vapor to prevent the asphyxia resulting from the more or less mechanical exclusion of air, a defect of the usual ether cone if too closely applied over the mouth and nose.

The exigencies of utilization of chloroform are different. Recent contributions to our knowledge of its toxicity have established as absolute the necessity of administering this agent in small (drop) doses, its vapor largely diluted with air.

That the successful chloroformization depends much more upon the skill and intelligence of the anesthetizer than upon the form of administration apparatus or special method, provided that the exhibition of the agent in small continuous doses be adhered to, is shown by the recently published report of the Anesthesia Commission of the British Medical Association. In this report in which the cases of narcosis are confined to the large English hospitals, where skilfully trained and expert anesthetizers are invariably employed, it is exceedingly interesting to note that the danger rates range from 1 to 2.14 per cent. regardless of mask, cone or compress methods.

The intricate physiological changes induced by any general intoxication sufficiently indicate that the safety lies far more in the experience and knowledge of the man, who controls the agent producing these phenomena, than in any mechanical device or routine method.

Let it suffice then to insist upon the pharmacological education and clinical training of this man, with an additional plea—other things being equal—for the simplest apparatus and method *always with small doses*. This would favor the adoption of the *compress* and *drop method* for the habitual exhibition of chloroform.

Ether and chloroform in small initial doses, acting upon the sympathetic nervous system, quicken the beat of the heart and produce a peripheral vascular congestion, perspiration and salivation. But both act promptly upon the cerebral cortex, stimulating the organ by irritation, excitement—action, but with a difference in degree of intensity and of time; chloroform shows the stronger and briefer irritation that of ether being more mild but prolonged.

A reference to the physiology of cortical irritation in the motor region reveals the consequent obligatory reflex action to be a quickened respiration in response to a feeble irritation, with an accompanying diminution of the depth of inspiration. If the irritation excitement becomes stronger or more prolonged the respiration is slowed with increasing exaggeration of the time and depth of the inspiration.

The same influence, which, transmitted by the pneumogastric nerve, affects the respiration in the maner above described, also reacts directly upon the heart which though increased in force is soon lessened in frequence by a moderate irritation of the cortex (ether). But a stronger irritation of this region stops the heart beat (the death of initial anesthesia by chloroform, *i.e.*, primary cardiac syncope).

Without wishing to deny the physiological fact of reflex irradiation from an irritated branch region to the production of a reflex pneumogastric arrest of the heart (the fatal naso-pharyngeal mucosa irritation attributed to chloroform) we can not refrain from pointing out the fact that primary cardiac syncope appears when all possibility of such irradiation reflex has been removed, (cocainization of the mucosa or section of the recurrent branch of the nerve), and we beg to insist upon the fact that the arrest of the heart is inevitably the physiological sequence of a strong irritation of the motor region of the cerebral cortex.

On account of the greater energy of intoxication possessed by chloroform in contra-distinction to the more moderate effect of ether, it is easy to conceive of a chloroform cortex irritation insufficiently strong (when the agent is administered in a too concentrated vapor) to provoke the direct physiological response to such a degree of cortical excitement, the immediate exertion of the pneumogastric function and its consequent cardiac syncope. While the lesser toxic

factor and energy of ether does not allow the possibility of its exhibition in sufficiently rapid or concentrated form to ever attain the necessary degree of *strong* cortical irritation which can and inevitably does produce the arrest of the heart, a full realization of these possibilities fixes indelibly upon the mind the peculiar necessity of minute doses and slow administration of chloroform until the first excitement stage of its anesthesia has been successfully passed.

This primary cardiac syncope is the great burden of responsibility under which the chloroform adherent must act. Little if any of this danger can be charged to ether.

The peculiar action of continued chloroformization in weakening disproportionately the auricular contractions of the heart, the resultant venous stasis, arterial ischemia and consequent paralysis of heart or respiration are so well described and verified in treatises of pharmacology that only a mention of these phenomena is needed here. Such description presents a most rational conception of the cardiac symptoms of secondary anesthesia, and sufficiently explains the danger of toxic doses or too long continued exhibition of chloroform.

It is very generally conceded that fatality of this order is avoidable by the skill of the anesthetizer and that the consideration of secondary syncope alone would leave the anesthetic in question decidedly less threatening than ether.

This latter agent, escaping the charge of exposing the organism to primary cardiac syncope offers, however, a tableau of progressive centrai depression with each stage and prolongation of its anesthesia. The heart and respiration in close coördination are diminished in frequence of action or volume of efficiency. The gradual loss of tissue function is evinced by their ischemia or cyanosis and the lowering body temperature. With the prolongation or depth of anesthesia, the continued depression becomes threatening and, more frequently than with chloroform, the progressive depression is not arrested by cessation of the exhibition of the drug, not even by energetic counterstimulation and the ultimate collapse of the organism is only kept from the list of ether fatality by its designation on the death-roll as *shock,* the prolongation of the period of increasing depression having permitted the removal of the victim from the scene of operation and possibly a survival of the narcosis period for several hours or days.

Thus progressive depression of ether with its final arrest of respiration is in all probability more frequent and inevitable than the secondary fatal accidents of chloroform. To ether also must be charged the numerous and often fatal complications induced by its specific irritation of the bronchial epithelium.

There is a growing consensus of opinion that if chloroform could be relieved from the accidents of primary syncope there would be little hesitation to admit its claim to be the master of anesthetics.

To accomplish this relief or find a more ideal agent of narcosis has become a most important object to the physiologist and surgeon.

To avoid the point of danger, the strong excitement of the cerebral cortex that accompanies the initial use of chloroform, English surgeons are employing nitrous oxide to induce the anesthesia which condition is then easily maintained with chloroform.

French physiologists have proposed to reduce the excitability of the motor-cortex by the preliminary drugging of the organism with atropo morphine, but the consequently inevitable coincidence of depressant effect of the atropine, morphine and the similar secondary action of either chloroform or ether narcosis, all of them acting as united depressants of the bulbar centers, can only be regarded with great suspicion of cumulative danger.

With the same object in view, to remove from the exhibition of chloroform its dangerous first stage, the strong cortical excitement, Dr. Hartman, Dr. Bourbon and the writer suggested and extensively used at Hôpital Bichat in Paris, since 1892, the remarkable agent of short narcosis, ethyl bromide. With this drug the initial anesthesia is rapidly induced without distress and can then be maintained with very minute doses of chloroform. For various reasons ethyl bromide appears to be particularly adapted for such purposes, relieving the initial danger factor of chloroform.

While the limits of our time prevent any special study of the physiological action of this last compound, we must stop long enough to point out, that by the ethyl radical, CH_3, CH_2, this bromide possesses all of the advantageous properties of anesthesia offered by ether, without the disturbance of mentality and slow induction which result from the contained oxygen of the latter molecule. And last, but of far-reaching importance, it must be remembered that ethyl bromide offers in every respect all of the particular pharmacological actions of the *bromides.* The same cerebral quiescence that is expected when alkaline bromides are exhibited is to be obtained with the same salt of the organic radical.

The possible consequences thereof strike us forcibly.

Here is the agent of anesthesia, ideal in its ease of administration, rapidity of action and perfectly safe for the induction of the unconscious stage which results without marked cortical excitement because of its suppression by the bromide quiescent action inherent to that drug, efficiently counteracting the influence of cortex-irritation otherwise to be expected by reason of its ethyl radical.

The extended use of ethyl bromide confirms more deeply this method of mixed anesthesia as fixed upon a sound physiological basis.

It must be said in passing, however, that the *absolute* necessity of a chemically pure compound is a reason for insistence upon a careful examination before use. So difficult is it to obtain a

perfectly pure ethyl bromide, that we, invariably, personally attend to its manufacture, if not able to know that the chemical has been freshly prepared for us by an expert chemist. The degree of skill which is essential for the preparation of this product in a state of purity to guarantee its physiological safety, is of such a high order that no preparation in this country would be considered safe unless personally prepared or guaranteed by a chemist of such marked ability as that of Dr. Kortright of the State University. Remember that chemists of sufficient ability in the organic field to be of value in a question of this class are exceedingly rare.

We repeat that *absolute* purity is the only condition by which ethyl bromide can be admitted as an agent of almost perfect safety for the induction of anesthesia. The dangers of its cumulative dose and consequent restriction to short narcosis have been previously explained.

For prolongation of unconsciousness, the narcosis induced by this bromide is easily and safely continued with chloroform in very small quantity. A teaspoonful of chloroform (in drop doses) is frequently all that is needed to continue the ethyl bromide induced anesthesia for the space of an hour.

The consideration of the molecular properties of anesthetics have so occupied our study that we cannot continue to encroach upon the time of this meeting to particularize the topic of analgesia, its uses in surgery, scope or limitations of application.

We can only remark that analgesia is apparently the property of all of the usual anesthetics. The wide range of "cortical or primary anesthesia," one of its methods of induction, attests that fact.

A new method of anesthesia, the spinal cocainization, awaits the consideration of the medical profession.

Of this, as well as of "cortical anesthesia," we hope to hear from others. If not, these two subjects must be laid over for consideration in a future paper.

LAGER BEER IN ACUTE VOMITING.

BY LOUIS KOLIPINSKI, M.D.,
OF WASHINGTON, D. C.

ACUTE vomiting is a severe symptom frequently encountered in abdominal and in female pelvic disease, in nervous disorders, and in acute general infections, with or without febrile reaction. To combat speedily and successfully this gastric derangement is the urgent duty of the medical attendant. A varied host of medicinal and dietetic remedies is at his command. Often, however, it is found necessary to alter one's mode of attack, often to withdraw in rapid succession various agents that fail. At times this symptom is so unmanageable that even a skilled and experienced clinician may meet defeat.

For these reasons, after long hesitation, but after a much longer trial of the remedy, the writer has concluded to call attention to the usefulness of lager beer in arresting obstinate vomiting. Its action is certain, intolerance rare. Its after-effects, as every one knows, are soporific. Attention was attracted to its virtue by the "craving desire for it" of some patients severely distressed with vomiting. Their request being complied with they expressed a feeling of great comfort and relief.

The beneficial effects are most marked in women and in those who are not habitual consumers of alcohol as a stimulant or intoxicant. Of the two varieties of beer—the pale and the dark—the latter is preferable. As to the quantity to be given, the amount need be but small, a bottle or two suffices. Singularly good results can be obtained from small doses. This is illustrated in the attacks of nausea, bilious vomiting, vertigo and sleeplessness, often a striking syndrome of epidemic influenza in women; a wineglass of beer, repeated in half an hour, will immediately soothe the disturbed organ and give a night of refreshing sleep.

The following shows its action in a case in which, all else unavailing, it cured.

A young man, twenty-five years of age, addicted to the cigarette habit and also a "graduate of the Keely cure," was seized at the end of a week's debauch of whisky, with bilious vomiting, insatiable thirst, abdominal soreness and pain. The stomach was intolerant of everything. The vomiting continued all day at intervals of ten or fifteen minutes. With the approach of night he was very much prostrated. The irritability of the stomach was increasing. He was given a glass of beer at 9 P.M.; water was withheld. The beer was repeated at intervals. He slept through the night. There was but one return of the vomiting and that at 2 A.M. The next day the patient had recovered.

As to the make of the beverage, the writer has no particular brew or brand to praise. In controlling vomiting he has not found any one's manufacture of especial value. In very severe and persistent vomiting, of four days' duration, caused by an inflammation of an ovary and Fallopian tube, immediate relief came after the patient had drunk the contents of three bottles of pale beer of inferior and adulterated composition.

CONSERVATIVE OPERATIONS UPON THE UTERINE ADNEXA.

BY HENRY T. BYFORD, M.D.,
OF CHICAGO.

IT IS very seldom necessary to remove the uterine adnexa for inflammatory disease. Although I believe that the sexual organs are of no benefit to their possessor, as far as promoting physical vigor or increasing longevity are concerned, there are many minor reasons for preserving them. I believe that after the age of thirty years these organs have already served

their function in stimulating individual development. After that age they are only of use to propagate the species, and, in functionating, act more or less as a drain upon the general system and tend to hasten senility. Yet women prefer, as a rule, to suffer with unhealthy organs rather than have them removed, and the prejudices of society are such that it is an unfortunate thing for a woman not to be able to retain them. I, therefore, consider it my duty to the individual patient to preserve sufficient ovarian tissue for normal function in women under forty years of age, even at the risk of their being obliged to undergo a subsequent castration.

There are three questions to be asked in determining what shall be done in a given case of disease of the adnexa that cannot be cured without opening the peritoneal cavity, *viz.*, (1) Shall we leave the ovaries and tubes intact and merely separate adhesions, replace the organs, etc? (2) Shall we remove the diseased portion of the ovaries and leave the best part of them, open up and clean out closed tubes, etc., and thus get rid of the diseased tissue without abolishing function? Or (3) shall we remove the diseased adnexa so completely as to bring on the menopause and prevent the monthly hyperemia?

There are undoubtedly cases in which the conditions require the complete abolishment of the monthly hyperemia of the sexual organs. Of these I will not speak. There are other cases in which separation of adhesions and suturing of the parts on a higher level may be all that is indicated. These I will also pass by. It is the second class of cases that I wish to consider, *viz.*, those in which the diseased portions of the ovary must be excised, the tubes made previous, and the patient left unaltered as far as her sexual functions are concerned.

Since peritoneal sections have become comparatively safe, it is not such a terrible misfortune if the patient should be obliged to submit to a second operation, and we are sometimes justified in recommending and performing conservative operations even when there is no certainty of a cure. We have also learned that purulent sactosalpinx is not a contra-indication to conservatism, for the pus in most cases has become sterile or is but feebly septic, and the communication of the tubes with peritoneal cavity and thus its usefulness as a transmitter of the ovum can be restored without danger or bad effects.

Severe septic cases of disease of the uterine appendages with habitual elevation of the body temperature, frequent acute attacks, large accumulation of pus, and complete disorganization of the tubal walls and ovarian structures should not as a rule be treated in a conservative manner.

Eliminating the septic cases just mentioned we have a very large majority left in which we can assure the patient that the diseased tissue can be removed or treated without interfering with her sexual functions or vigor. This I consider one of the chief advances made in modern gynecological surgery.

When there is for any good reason an objection to an abdominal incision, the same work can often be done by the vaginal route, although the abdominal operation more often gives good results.

The only argument which I care to advance in this short study is that we are doing such operations and that the immediate as well as remote results are good. Before abdominal sections were performed for adherent appendages, gynecologists recorded a large percentage of symptomatic cures without any operation, and now that we are operating in a conservative way we are likewise observing a large percentage of cures without complete removal. In other words, we are becoming more and more convinced that complete castration is to be reserved only for extreme cases.

I will only take up your time with two cases representative of many others which I am constantly performing. Dr. A. Palmer Dudley of New York has also reported a number of operations for pyosalpinx. It was his pioneer work that encouraged me to extend my conservative operations to adherent and occluded tubes.

I was called to see Miss H. in April, 1898, and found her in bed. She had been broken down in health for a year or more, and had taken local treatment and the rest cure without benefit. Her local symptoms were dysmenorrhea and pelvic pain. A consulting gynecologist of wide experience had recommended removal of the ovaries and uterus as the only means of getting her out of her deplorable condition. I found double oophoritis, a small cervix and moderate uterine hyperplasia. I dilated the cervix, curetted the uterus, made a peritoneal incision through the posterior vaginal fornix, and removed about two-thirds of each ovary, leaving only what seemed to be healthy tissue. The patient recovered promptly, married in a year, and has been well and hearty since.

In another case, that of Mrs. J. S. S., on February 15, 1901, I did an abdominal section and found both tubes occluded. The right tube contained cheesy matter and its walls were thickened and hardened from interstitial inflammation. The left tube contained a little turbid mucus. The left ovary contained a hematoma the size of a walnut. The appendages of both sides were extensively adherent. I separated the adhesions, removed a large part of the right ovary, opened the fimbriated extremity of both tubes by incisions, and sutured the mucous to the peritoneal coat in order to insure permanent patency. The contents of the tubes were pressed out, and the cavities syringed with sterile water. The peritoneal cavity was closed without drainage. The patient walked about the room at the end of three weeks. Her immediate recovery was about as rapid and complete as in those cases in which the ovaries and tubes are removed *in toto*, she continues well, and complains of no symptoms whatever.

100 State Street,

ACUTE EDEMA OF THE UVULA, PALATE, PHARYNX AND EPIGLOTTIS, FOLLOWING THE EXCESSIVE APPLICATION OF ADRENAL SOLUTION PRESERVED WITH CHLORETONE.[1]

BY SOLOMON SOLIS COHEN, M.D.,
OF PHILADELPHIA.

THE folowing report of an isolated observation may be of interest in view of the wide and increasing use of the various preparations of the adrenal gland, which, as one of the pioneers in these therapeutic applications, I have employed freely and do employ freely with the confidence born of repeated demonstration.

Rev. Father X. has been under my care for a number of years for recurring attacks of asthma. The patient is stout and plethoric, although active mentally and physically. In addition to asthma he was troubled with hoarseness and, at times, difficulty in phonation. When first seen, examination of the heart revealed no structural change, but somewhat feeble action; examination of the lungs elicited the usual phenomena of spasmodic asthma; examination of the nose disclosed no significant abnormity of structure, but considerable general congestion and slight turgescence of the middle and lower turbinates. Examination of the larynx showed thyro-arytenoid paresis of slight degree, and what, at first sight, appeared to be two papillomata symmetrically located on the two vocal bands posteriorly at their insertions into the arytenoids. The larynx was congested throughout. Spraying with adrenal solution, made extemporaneously, reduced the congestion, and it was seen that the apparent papillomata were simply circumscribed, boggy relaxations of the mucous membrane. These retained their pink color, though the hue was of lessened intensity, The diagnosis was confirmed by Dr. J. Solis Cohen, who, later, saw the patient in consultation. Under treatment, which included appropriate general medication, the application of astringent solutions locally, faradic applications over the larynx externally, and the use of adrenal extract internally, the patient improved rapidly. Recurrences of asthmatic paroxysms became less and less frequent, the voice became stronger and clearer, complete approximation of the vocal bands was made, the protuberances having become much smaller and the right passing under the left in phonation. The patient, who had been working very hard, establishing a new school in his parish, in addition to his ordinary priestly duties, was advised to take a long vacation. He made a winter cruise to the Mediterranean regions, returning thoroughly well, except for the condition of his larynx. He was then placed under the care of a teacher of vocal exercise, and continued to improve in all respects except that after prolonged use of the voice in church services or upon pastoral visitations, and occasionally after exposure to cold and wet, the larynx would become intensely congested, and asthmatoid symptoms would recur, though not with such severity as to warrant calling them attacks of asthma. In order to ward off such recurrences, the patient was given a solution of adrenal substance in glycerin and water, prepared by Mr. F. E. Morgan, the well-known pharmacist of Philadelphia, and instructed to use it as a spray, more or less constantly, preceding the spray of zinc sulphocarbolate in rosewater that he was using twice daily; which he did with good results. When Messrs. Parke, Davis & Company placed upon the market their solution of suprarenal substance preserved with chloretone, this was substituted for the glycerin extract formerly used. One night I was called in haste, being told that Father X. had a very severe attack of asthma and could scarcely get his breath. The appearance of the patient was different from that presented in ordinary attacks. The face was very much flushed, but dusky; the breathing was evidently painful, and there were slight inspiratory stridor; asthmatic râles were not evident, though the stridor made in the larynx was heard over the chest. Upon examination the uvula was seen to be swollen to about three times its ordinary size, evidently much distended with fluid. In color it was nearly white. The palate and half arches and a portion of the posterior wall of the pharynx were likewise markedly edematous, and there was slight edema of the epiglottis. The interior of the larynx, fortunately was clear. The patient stated that he had gone through a period of very great use of the voice, that his throat had begun to feel uncomfortable, that he had sprayed the pharynx and nasopharynx very vigorously and for a prolonged period, possibly three or five minutes, with the suprarenal-chloretone solution. No effect upon the heart seemed to have been caused by the application. The uvula and palate were scarified in several places, but little fluid exuded, and scarcely a drop of blood. It was not deemed necessary to scarify the epiglottis. The patient was advised to keep at rest, a drastic purge was given, and gargling with lukewarm water, aromatized with toilet vinegar, was advised. In about an hour, whether spontaneously or otherwise, the edema began to subside sufficiently to permit of greater ease in breathing; if, indeed, the visible edema was the direct cause of the difficulty, and not merely an indication of a general condition of the respiratory mucous membrane which subsided with it. In about an hour more the patient was feeling very comfortable, and I felt warranted in leaving him. Traces of the edema of the uvula were visible for three or four days.

While I am of the opinion that the condition described was due to the effect upon the blood-vessels of an overdose of suprarenal solution, and possibly to the concomitant influence of the chloretone, I have not felt justified in making any experiments to determine the point. The patient was instructed to go back to his old preparation, and to use it with moderation, since which time no further bad symptoms have occurred. The

[1] Read by title before the American Laryngological Association.

solution to which I have referred is not that of adrenalin chloride now available, but the extract of suprarenal substance with chloretone which was previously placed upon the market. I have used the adrenalin chloride solution as prepared with much satisfaction in the treatment of hay-fever and other relaxing conditions, in various strengths, from 1-1,000 to 1-5,000, and have not observed any ill-effect either from this or from the chloretone accompanying it.

MEDICAL PROGRESS.

Proteolytic Action of Bacteria.—This subject is of interest from the standpoint of the relation of intestinal bacteria to the digestion of albuminoids. Much experimental work has been done in this direction, the most recent coming from Ernst Cacace (*Ctlblt. f. Bak.*, Aug. 26, 1901). He has investigated the proteolytic action of the sarcina aurantiaca, bacillus anthracis and staphylococcus pyogenes aureus. He cultivated these on a 10-per-cent. aqueous solution of gelatin and also on coagulated cow blood-serum. He employed for the inoculation of these media pure agar cultures of these organisms in large amount. In such inoculated blood-sera he found proto-albumins and deutero-albumins in large quantities and also traces of peptone. In the gelatin growths there were present proto- and deutero-gelatins with traces of gelatin peptone. He believes that proteolysis is a property of all living beings.

Foreign Bodies in the Nose and Ear.—The general practitioner is frequently called upon to remove foreign bodies from the nose and ear, and it is well known that unskilful management of such cases has probably caused more injury than the presence of the annoying bodies. P. Fridenberg (*Med. Rec.*, Sept. 21, 1901) deprecates the use of forcible syringing to remove bodies from the nose. Direct syringing of the obstructed passage through the anterior nares or, better still, through the pharyngeal opening by means of a post-nasal syringe is much safer and better. Drawing a tampon of moistened gauze through the nasal cavity, according to Sajou's method, is frequently successful. Direct extraction by instrumental efforts must then be tried and a strong bent probe, a hook or wire loop or a blunt curette may be passed between the nasal wall and the foreign body. It may be necessary to push it back into the nasopharynx, but care must be taken that it does not enter the larynx. The forceps or galvanocautery may be used to diminish its size and in some cases of rhinoliths chemical agents may be employed. Insects and maggots are best treated by chloroform injections, pure or in mixture. Foreign bodies of the ear seldom necessitate immediate removal and no hurried unskilful operation should be attempted. In most cases repeated syringing with a warm boric-acid solution to which lysol or soap has been added is successful. A large perforation is practically the only contra-indication to syringing. Instrumental removal should be done only with the greatest care.

Idiopathic Dropsy.—Although this condition is mentioned in a good many textbooks on medicine, it seems not yet to have been given the consideration which its gravity and frequency warrant. W. P. Herringham (*Brit. Med. Jour.*, Sept. 7, 1901), after carefully reviewing the histories of the few recorded cases, concludes by asking and answering the three following questions: (1) Is the disease really nephritis? (2) Is it in any case entirely dependent upon anemia? (3) Is it a condition distinct from either? (1) Both symptomatically and etiologically the disease closely resembles nephritis. Moreover, in not a few cases of post-scarlatinal nephritis, in which the urine was free from albumin, the necropsy showed well-developed kidney disease. This, however, is not true in every case and it is now generally admitted that a considerable number of children who die with every evidence of nephritis following scarlatina carry a good pair of kidneys with them to the grave. (2) It is absurd to suppose that anemia can develop to a sufficient degree to cause dropsy in the case of healthy men who sometimes suddenly develop this symptom ofter a wetting. Furthermore in a considerable number of cases of dropsy there is no anemia. (3) Even supposing that all cases of dropsy could be explained by anemia, or nephritis, or cardiac lesion, we are very much in the dark as to the ultimate cause. No one has ever seen the damage done to the endothelial cells, nor has the hypothetical toxin as yet been separated. It seems reasonable that there is some as yet undiscovered ulterior cause which produces the three symptoms, nephritis, anemia and edema, the latter being coincident with, not consequent upon, the first two.

Disadvantages of Copper Sulphates in Diseases of the Eye.—In a recent article in the *Medical Record* Dr. Claiborne extols the use of copper sulphate in many chronic inflammatory conditions of the conjunctivæ, especially trachoma. C. Williams (*Med. Rec.*, Sept. 21, 1901) takes exception to the conclusions which were there reached and characterizes the use of that remedy as a relic of barbarism. He says that there is nothing which it can accomplish which can not be done with infinitely less pain and in a much shorter time, by other means. He cites numerous examples where prolonged use of copper has been unavailing, although always extremely painful and frequently causing corneal ulcers or even a serious iritis. He believes that trachoma is most successfully treated with weak solutions of silver nitrate together with frequent irrigations with bichloride solution in normal salt. No application to inflamed conjunctivæ causing pain of lasting duration should be countenanced. Expression is not absolutely essential, yet much hastens the cure of trachoma. The most difficult part in the cure of trachoma is the finishing and this can best be accomplished by a solution of tannic and boric acid in glycerin and water. When it is desired to stimulate the cornea to increase

tissue changes, alcohol may be added. No staining from silver solutions has been seen even when their use was kept up for a long time.

Use of Tuberculin.—In 1890 the world was surprised by the report from that eminent authority, Robert Koch, that he had obtained a specific cure for tuberculosis in the form of the so-called tuberculin. The universal thankfulness was soon dispelled by the opposition which was developed and lead by Virchow. Since then the use of tuberculin in the treatment of cases of tuberculosis has been very limited and its practical application in this country has been, in general, restricted to diagnostic purposes. G. A. HERON (*Phil. Med. Jour.,* Sept. 21, 1901) believes that much injustice has been done in condemning the general use of tuberculin and, after considerable experience and many successful results, expresses the opinion that it has fallen into disrepute (1) on account of its frequent use in unsuitable cases; (2) by its administration in too large doses: (3) by neglect of the rule that it should never be given until the patient's temperature has been normal for the previous twenty-four hours, at least; (4) by neglect of the rule that the dose should gradually be decreased instead of increased when its use is followed by a rise of temperature. It is never to be recommended in any case of severe involvement by consolidation or where there is any excavation. Its use in selected cases is still highly recommended and as an assistant in diagnosing early cases it is certainly invaluable.

Tuberculosis in Infancy.—Cases of tuberculosis during the first six months of life are very rare, but are common toward the end of the first and during the second year, according to D. DIEUDONNE (*Münch. med. Woch.,* Sept. 10. 1901). This may be easily explained by the fact that the children then begin to expose themselves to infected dust by crawling about the floor, that skin lesions such as herpes, impetigo and eczema are frequent and form a ready portal of entry, and that the nasal and oral secretions are abundant, incident to dentition, and form a ready means of retaining the germs. Small sterile sponges were rubbed over the hands of suitable cases and also allowed to imbibe their nasal secretion and cultures then made, with the result that 5 out of 88 showed the tubercle bacillus. The importance of guarding children, especially those of tuberculous parents, against such infection, is emphasized.

Heart in Caisson Disease.—A number of perfectly healthy caisson workers were examined by B. HORNUNG (*Münch. med. Woch*, Sept. 10, 1901) to see if the increased atmosphere caused any change in the size of the heart. Increased cardiac dulness in all directions was found in most, the greatest increase being toward the right. When the atmospheric pressure was increased suddenly, instead of gradually, the same facts were noted, but in a few cases the dilatation was still more marked. In all, normal heart limits were found after sixteen hours. The author thinks it possible that the labyrinthine symptoms of caisson disease are due to the circulatory changes and not to increased pressure on the labyrinth.

Membranous Dysmenorrhea. — Concerning membranous dysmenorrhea, D. KOLLMANN (*Münch. med. Woch.,* Sept. 10, 1901) sets up the following rules: (1) There is no connection with pregnancy and abortion and sterility is not necessarily the result, nor is there any relation to inflammation of the mucosa of the uterus; (2) the membranes are a manifestation of the necrosis caused by hemorrhage and exudation into the tissue; (3) the cause of the pain is not to be found in the tearing off of the membranes; (4) the anatomical picture does not correspond to any definite type and can vary with the same patient; (5) the condition is frequent and often overlooked.

Intestinal Disinfection.—For the estimation of the degree of bacterial activity going on in the intestines, three methods are available, namely, the quantitative determination of ether sulph-acids and indican, the bacteriological investigation of the feces and determining the toxicity of the feces by Bouchard's method. The first method has the disadvantage that many supposed antiseptics introduced into the gut are changed into simular bodies, thus making an investigation of their activity an impossibility; the second method gives results varying within too wide limits to be practicable, and the last is difficult, because the actual toxic products have not as yet been isolated. H. SINGER (*Therap. Monatshft.,* Sept., 1901) recapitulates the various so-called intestinal antiseptics that have been recommended, from calomel up to the many new drugs, and shows how none have fulfilled the expectations that were placed in them. Even high irrigations of the intestines are inefficient and open up the danger of intoxication from the antiseptics added to the water.

Determination of Blood.—To ascertain the presence of blood, especially in feces, C. STRZYZOWSKI (*Therap. Monatshft.,* Sept., 1901) recommends that one drop of 1:500 sodium iodide be added to the particle, and that, after the addition of concentrated acetic acid, the slide be boiled for from three to six seconds. There will result deeply-stained egg-shaped, biconvex crystals which can readily be recognized. Instead of the iodide, hydriodic acid may be used, and, with feces, it may be necessary to remove the fat with equal parts of chloroform and ether. If the above method gives a negative result, resort must be had to the spectroscope and the ozone reaction. The author has made various experiments to determine how high blood may be heated before the various reactions disappear. He has found that above 190° C. hemin crystals no longer form with the method above described, and that even at this temperature the crystals are often atypical, in the form of needles or balls. At 210 to 220° C. the spectroscopic and the chemical determination with tincture of guaiac and old oil of turpentine no longer are possible.

Mosquitoes and Their Properties.—An interesting article on mosquitoes as they occur around New Orleans has been written by H. A. Veazie (*New Orleans Med. and Surg. Jour.*, Sept., 1901). After a few general remarks on the general technic of catching the insect with short wide-mouthed test-tubes, keeping them for study in large bottles with sugar and water, killing them with chloroform, preserving the specimen from moths in wooden cigar-boxes, and examining them under the microscope in the ordinary dry cell, the author goes into a detailed anatomical description, pointing out especially the well-developed sharp epipharynx or stinging apparatus of the female and its more blunt counterpart in the male. The two most common genera found are the *Anopheles* and the *Culex*, and of both there are many subdivisions. The position which the different genera take while resting is usually distinctive, as the *Anopheles* usually rests with its body very nearly at right angles to the surface, while the body of the *Culex* and others is more parallel. The *Anopheles* also is quite awkward on alighting, whereas the *Culex* seems to have less trouble in coming to rest. All mosquitoes come from an egg which hatches and forms the larvæ; this changes into the pupa and from this the imago or mature form of the insect develops, the moult skin being used as a float until the wings and other parts have time to unfold, dry and adjust themselves to a new existence, so that water is an absolute necessity for their development. The most common breeding-places are the gutters, drainage-canals, water-closets and cisterns; very few, if any, come from our rivers and lakes on account of the wave, winds or depth of water and myriads of fish which feed upon them, among which minnows are especially prominent. In considering prevention and remedies, all efforts to get rid of mosquitoes should begin about April 1st. The gutters should be kept either dry or with running water, but never stagnant, for the female cannot well alight on running water to oviposit; the cisterns should be covered with fine galvanized iron wire gauze, which is better than oil, and the water-closets should be treated once a month with an ounce or two of petroleum. Where stagnation is unavoidable, coal oil should be freely poured on the surface.

A New Gynecological Speculum.—A self-retaining speculum, which renders emergency operations possible without the aid of assistants, is described by A. Garioni (*Centralblatt f. Gyn.*, 1901, No. 36). Its parts are all detachable, so that its aseptic properties are up to the highest standards. It most resembles Collin's speculum, but has shorter blades. The essential parts of this instrument are as follows: (1) Two short, medium wide blades, spreading in the transverse diameter of the vagina, with a wide flaring shoulder on each, which, when the instrument is introduced, lie on the vulva and buttock; (2) a horizontal crosspiece, fastened to the upper edge of each blade at the angle where the flaring shoulder turns outward, on the left blade by a pivoted separable hinge joint, on the right blade by a slot where a thumb screw works which opens the blades in parallel position; (3) a screw and thumb-nut attached to the left blade, which separate the tips of the blades in the usual manner in the vault of the vagina; (4) a pair of volcellum forceps, with scissor handles bent on the flat at right angles to the axis of the jaws, so that the handles are upon the buttock of the patient entirely out of the field of treatment; the upper jaw of the volcellum forceps is provided with a large number of pivots which serve to catch the instrument and to maintain the cervix uteri drawn toward the vulva, in degree varying with each case; (5) a retaining catch to receive these pivots on the volcellum forceps fastened to the horizontal crosspiece; (6) a douche nozzle which may be attached to the volcellum. The application of the instrument is as follows: Introduction of the blades up to their shoulders, parallel separation of them until they are at or near the tuberosities of the ischii, angular separation of their tips in the vault of the vagina, seizure and forward traction of the cervix uteri with volcellum, adjustment of the same on the catch, attachment of the douche nozzle if desired, for operating or treating under continuous current. Hence without ever troubling a second party to hold instruments, any ordinary gynecological procedure can be done by one person and yet all the necessary and usual advantages of an assistant are present.

Congenital Macrodactylia.—According to some writers congenital macrodactylia is a purely teratological condition. In the opinion of Boinet (*La Presse Méd.*, Sept. 4, 1901) it may with at least equal propriety be regarded as pathological, inasmuch as it is characterized by a progressive growth, ordinarily more rapid than that of the remaining normal fingers, and exceptionally rapid during adolescence. Macrodactylia is rarely hereditary. It is more frequent in males than in females. In many instances there is no accompanying anomaly of the skin; secretion and sensation remain normal. Radiography has shown in some instances bony hypertrophy without osteophytes; in other cases osteophytes were present, with rarefying osteitis. The pathogenesis of macrodactylia has not yet been clearly elucidated.

Gold Wire in Herniotomy.—One hundred and twenty consecutive primary-union herniotomies, in which buried gold-wire was the suture used, are reported by G. de Francisco (*Centralbl. f. Chir.*, 1901, 36) for J. Tansim. In addition he has devised and for years satisfactorily used self-retaining and self-acting retractors for the muscles and an elevator or hook for the cord. A long-handled spatula serves to press the deep structures out of the way during the sewing. The plan of the instruments is briefly considerable weight for their retention and traction and a generous depth for their hold on the tissue. They obviate handling the wound, preserve asepsis and tend to promote primary union.

Radical Cure of Cystocele by Temporary Suspension of Bladder.—This operation was practised on a woman, aged sixty-three years, who had a cystocele the size of a large orange protruding from the vulva. This condition had existed for six years; during most of this time relief could be obtained only by having the patient remain in a recumbent position. In performing the operation, dissection was begun anterior to the cervix uteri, as for hysterectomy. The peritoneum was stripped from the bladder with the finger and blunt instruments. The wound was packed with gauze. The abdomen was then opened in the lunea alba for a distance of five inches immediately above the symphisis pubis. The bladder, distended with sterile water, was grasped with dull forceps and drawn forward. Sutures were passed through the muscular coat of the bladder on either side of median line for a distance of 1½ inches, three-quarters of an inch from the median line and parallel; the ends were held outside the wound. The outer coat was next denuded in median line between the sutures, when by means of a semi-curved ligature carrier the free ends were carried through the abdominal wall, their exit made to correspond with the position of exit from the bladder, and the ends secured by locked forceps dropped to sides of abdomen. The wound was closed by subcutaneous continued suture. The free ends of the suspension sutures were drawn taut and fastened over rolled bolsters of sterile gauze. The patient was then placed in Sim's position and the gauze packing from the vaginal wound were removed. The abraded surfaces of peritoneum were approximated by catgut, and colporrhaphy followed. A narrow opening was left for drainage of the space in front of the bladder. On the thirtieth day the silkworm gut ligatures were loosened and withdrawn and the patient was discharged the fortieth day. J. B. TAULBEE (*Amer. Gyn. and Obstet. Jour.*, Sept., 1901) states that the most difficult features of the operation are in properly divesting the bladder of its peritoneal covering and re-approximating the same, and properly inserting ligatures and denuding the area which is to adhere to the pelvic or abdominal fascia. Priority for the operation is claimed.

The Blood in Surgical Diagnosis.—The results of extended collaboration in this field and the following summary are given by R. C. CABOT, J. B. BLAKE and J. C. HUBBARD (*Annals of Surgery*, Sept., 1901). (1) At the end of complete anesthesia there is occasionally a slight, rarely a marked leucocytosis; (2) at the end of the operation there is a considerable leucocytosis in one-half the cases, and almost always a distinct increase over the number found at the end of complete anesthesia; (3) the blood at the end of operations for malignant growths is not necessarily much impoverished and in favorable cases usually recuperates rapidly; (4) hourly variations in the white-cell count may occur in conditions other than the preperforative stage of typhoid fever and may be present in health too; (6) very violent physical exertion produces conditions in the blood which pass the normal and may be identical with that found in disease. This last conclusion is derived from a study of the blood of the runners at Marathon in the recent Greek games by R. C. Larrabee.

Plantar Reflex and Babinski's Sign.—Babinski was the first to record the pathological alteration in the plantar reflex, whereby in certain cases mild irritation of the sole of the foot produces not plantar flexion, but dorsal flexion of the toes, and especially of the great toe. The cause assigned by Babinski for this alteration of the plantar reflex is in almost every case some lesion of the pyramidal tract; recognized exceptions are epilepsy, strychnine-poisoning and other diseases producing exaltation of reflexes, and normal infancy. H. SCHNEIDER (*Berl. klin. Woch.*, Sept. 16, 1901) took advantage of the opportunity to record the Babinski phenomenon in nearly a hundred cases of disease of the central nervous system. He states that this phenomenon may be caused in two ways; first, by interruption of the pyramidal tract or disease of the motor cortical area, thus destroying the normal plantar flexion, which is a cortical reflex; second, by diseases which either increase the irritability of the motor cells of the spinal cord, or diminish the irritability of the cerebral cortex. Briefly stated, Babinski's phenomenon is the substitution of a spinal for a cortical reflex. It is due to the relative suppression of the cortical reflex, a phenomenon which may or may not involve distinction of cortical centers, and which may or may not point to a lesion of the pyramidal tract. In conditions producing general heightening of spinal reflexes a diagnosis of pyramidal lesion cannot be based on Babinski's sign.

Tubal Gestation Sac Anterior to the Uterus.—A surgical curiosity which is doubly interesting because fully diagnosed before the operation is reported by A. H. G. DORAN (*Lancet*, Sept. 14, 1901). It consisted in a tubal gestation in which the sac lay anterior to a retroverted and flexed uterus and had adherent to it an inflamed appendix. This is certainly a rare combination, but his report serves to remind us that diagnosis must always have reference to complicated conditions.

Comparative Virulence of the Tubercle Bacillus from Human and Bovine Sources.—The relation between the various types of the tubercle bacillus found in man and in the lower animals has been the subject of much discussion for several years past. A careful study of the comparative virulence of the organism from human and bovine sources has been made by M. P. RAVENEL (*Univ. of Penn. Med. Bull.*, Sept., 1901). He finds that cultures from these two sources differ markedly in pathogenic power, the bovine bacillus being more active than the human for all species of experimental animals with the possible exception of swine, which are highly susceptible to both. Tuberculous material from cattle and from man corresponds closely in comparative pathogenic power to pure cultures of tubercle bacillus

from the two sources. The author regards it as a fair assumption from the evidence at hand that the bovine tubercle bacillus has a high degree of pathogenic power for man also, which is especially manifest in the early years of life.

Fracture of the Skull.—This subject is discussed by W. Lathrop (*Annals of Surgery*, Sept., 1901) from the standpoint of the advantages of early operation, even in doubtful cases. Such beneficent and often life-saving procedures are possible only to modern asepsis and antisepsis. Every comatose case brought into a hospital may be suffering from apoplexy, concussion or contusion of the brain and uremia. The last condition is ruled out at once if urine is drawn by catheter and found to be negative. The other three are differentiated only by their degree and subsequent course. In doubtful cases where there is history of injury to the head, with persisting or increasing symptoms, it is always advisable to operate at the seat of the traumatism. When the inner table is much comminuted, the dura usually suffers and the brain beneath it. Sometimes, however, the dura shows rare resisting powers, although the brain beneath it may be badly torn and bleeding. In such cases an unusual elasticity or tension of the dura appears as soon as the outer surface of it and the wound area are cleaned up. The very great weight of certain symptoms can not be overstated and consequently the surgeon should always be alert to detect their primary presence and their later development and progress. In general such are the signs of the local brain injury. The prognosis is good when the operation is done early and the fracture or hemorrhage has in general not damaged more than the surface of the brain. Subnormal temperature followed by a rapid rise, persistent coma, paralysis, deep and irregular breathing, pupillary dilatation are nearly always of fatal significance. A temperature at or above normal, rising one or two degrees with regular respiration and full and slightly accelerated pulse are usually favorable features.

The Use of Raw Milk in Enteritis and Athrepsia.—In the process of sterilization of milk, casein loses the property of coagulation, nuclein and lecithin become insoluble, lactose is completely changed and the fat collects in droplets on the surface. While many authors believe that the digestibility of milk so altered is not diminished, this supposition is not borne out by the clinical experience of Jensen, Von Starck, Heubner and others. S. Monrad (*La Presse Méd.*, Sept. 4, 1901), after treating five infants unsuccessfully with sterilized milk, was led to substitute raw milk. The result was rapid and excellent; vomiting ceased, the bowels became regular, the patients regained weight which they had previously lost. The author, however, does not recommend the unqualified suppression of sterilized milk, but advises the substitution of raw milk in cases where infants prove intolerant of the sterilized variety and suffer from intestinal catarrh and athrepsia.

Blood Changes After Antityphoid Inoculation.—These changes are summarized and their bearing explained upon the all-important subject of serumtherapy in general by A. E. Wright (*Lancet*, Sept. 14, 1901). (1) When the quantum of antityphoid vaccine employed is so great that it produces the well-known and intense systemic symptoms, the inoculation will be followed by a period of decreased bactericidal properties in the blood and consequently by an increased susceptibility to typhoid infection over the same period. Upon this negative phrase there may be expected to succeed after a lapse of about three weeks a positive phase of increased bactericidal power and augmented resistance to typhoid infection. (2) When the quantum of antityphoid serum produces a series of still more intense constitutional reaction, it may be succeeded by a negative condition of the blood, which may persist indefinitely or never be followed by a positive phase. This same phenomenon has been observed in patients who go through a severe degree of typhoid fever. (3) When the quantum of antityphoid serum employed is such that no severe degree of systemic effect is produced, the injection may be expected to produce a positive bactericidal phase at once, with no preliminary negative phase, and sometimes as promptly as within twenty-four hours. From the vastly important premises he deduces these conclusions: (1) Inoculations producing the highest degree of general effect are at all times not advisable and in the presence of a typhoid epidemic would be a certain source of danger; (2) inoculations producing a marked but not an extreme reaction are in the same way not advised in the presence of an epidemic. When, however, several weeks are to elapse before known exposure to the disease shall occur or when a second inoculation can not be carried out, then they should be always resorted to. (3) Inoculations which do not produce any or only a slight systemic reaction are those whose employment is most appropriate at all times, when their repetition is possible, and particularly during the rage of a typhoid visitation. These three principles are in accord with the observations of Ehrlich in the action of tetanus antitoxin in goats and of Haffkine in the antiplague inoculations. It is probable that they underlie the correct method of all immunization with serums and antitoxins. (4) When, after a recovery from enteric fever, a patient's blood is found too deficient in bactericidal power, it is advisable, especially in the presence of a continuing typhoid epidemic, to raise the standard of blood-resistance by appropriate inoculations. (5) On the other hand with high or very great blood-resistance after a recovery it is not necessary to inoculate, with the hope of raising a bactericidal power already up to the standard. (6) The efficacy of any antityphoid vaccine, as the result of age or method of storing and preparation, is a question which can be decided only by an inoculation with it, followed by an observation of the actual bactericidal power present in the blood.

Cause of Osteomalacia.—Since this rare disease occurs more frequently in women during pregnancy and especiallly in the poorer and ill-fed classes, J. G. DRENNAN (*N. Y. Med. Jour.*, Sept. 28, 1901) suggests that perhaps this disease of decalcification is due to the abstraction of calcium salts from the mother's blood by the fetus. It is not probable that the fetus abstracts nourishment from the tissues of the mother, but indirectly from the pabulum which she requires to rebuild her own tissues. Osteomalacia then would be the result of a poverty of calcium salts in the blood of the mother, by which her osseous system is starved by the fetus assimilating all the available salts.

Pernicious Anemia in Infants.—In citing one of these rare cases of a child, aged nine months, T. M. ROTCH and M. LADD (*Archives of Pediatrics*, Sept., 1901) emphasize the following points: The insidious onset with moderate and paroxysmal attacks of indigestion, the extreme pallor, great loss of strength, slightly elevated temperature for months and absence of glandular or splenic enlargement or of any demonstrable cause for a secondary anemia. The blood showed the typical characteristics of pernicious anemia, with not much leucocytosis. Under treatment with oxygen, the saccharated carbonate of iron, ferration, etc., the blood and general symptoms improved until the infant appeared in all respects sound and healthy. This child has been put on artificial food at four and a half months. In making a diagnosis of pernicious anemia in infants, signs which are almost pathognomonic in adults lose significance, on account of the greater instability of the infant's blood-making function. Megaloblasts, normablasts, macrocytes and poikilocytes may occur in grave anemias other than "pernicious"; still, these elements are needed for diagnosis. In the treatment, feeding is of first importance, and arsenic if tolerated, and iron in the form of ferration or a similar preparation may be of benefit. In this case the oxygen inhalations seemed to give prompt improvement.

Hereditary Chorea.—Three cases, each showing well the hereditary character of the disease, the insidious onset, and the late mental impairment, are reported by C. E. RIGGS (*Jour. of Nervous and Mental Disease*, Sept., 1901). Mental stress or shock preceded the onset in two of the victims, who were women. One of these showed marked incoördination of gait if at all fatigued. Both were very untidy in dress, were mentally sluggish, and showed Romberg's symptom and exaggerated deep reflexes, speech, respiration, and arm-movements were jerky in all the cases.

THERAPEUTIC HINTS.

Overextension in Pott's Disease.—Continuous, gradually-increased overextension of the spine is, according to ROYAL WHITMAN (*Pediatrics*, Sept. 1, 1901), a most effective treatment, and at the same time one quite at the command of the general practitioner. The vertebral bodies do not grow again, but the pressure and friction which stimulate the destructive process is removed. The method is especially applicable to children under three years, as these can be kept in the recumbent position. The apparatus is a rectangular frame of gas-pipe, rather longer and narrower than the patient, and covered with tightly-drawn cotton sheeting except for a six-inch interval at the center. Thick pads of felt are sewn so as to support the body at each side of the kyphotic area. As soon as the patient has become accustomed to the restraint, the bars are from time to time bent upward beneath the kyphosis with the aim of separating the diseased vertebral bodies and obliterating the normal curves of the spine. The child's clothes are made to fit over all, and the arms and legs need no restraint. Once a day the child is removed, is carefully turned face downward upon a large pillow, and the back inspected and powdered.

Cooked or Raw Meat in Tuberculosis.—Following the diverse statements regarding the relative merits of raw or cooked meat, CORNIL and CHANTMESSE (*Gazette Médicale de Paris*, Aug. 31, 1901) inoculated numerous dogs with the tubercle bacillus. Then the dogs were separated into pairs, the two of a given pair being practically of equal weight and age. One of the animals of the pair was allowed to eat cooked meat to satiety, and the other given the same weight of raw meat. It was noticed that the meat lost about 20 per cent. of its weight in cooking. The dogs fed on cooked meat succumbed in from four weeks to five months, and the autopsy showed generalized tuberculous lesions with caseation, and very marked fatty degeneration of the liver. When a dog fed on cooked meat died, his companion fed on raw meat was killed, and in every case the latter animal was much better nourished, the fatty degeneration of the liver was less, and the tubercles were less numerous, of smaller size, and showed less caseation. One animal fed on raw meat preserved its vigor and healthful appearance at the end of a year, it having been spared though its companion fed on cooked meat had succumbed at five months. These experiments go to show that superalimentation is not the essential, but that raw meat possesses remedial qualities not found in cooked meat.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

LONGEVITY AND INSURANCE.

In spite of the brilliant analysis of Schopenhauer who so clearly demonstrated the inability of the ordinary man to distinguish pleasure from pain, there still exist occasional deluded mortals who cling with pathetic obstinacy to the ancient superstition that life is worth living. Such may find both interest and gratification in a brief review of the evidences of increasing human longevity which, in civilized communities at least, have formed one of the notable characteristics of the progress of the last century.

Of a general nature is the fact that famines and epidemics, which in times past sometimes decimated the populations of enormous areas, have steadily become more local and transient, so that now the threat of their recurrence excites only mild apprehension on the part of the public. Wars also, though unhappily still too common, are certainly less numerous and protracted than of yore, while the inevitable loss of life involved in their prosecution is being rapidly reduced to a minimum by the modern policy of screening noncombatants, so far as practicable, from the direct effects of military operations. Again, the annual slaughter of the innocents which, particularly in cities, attends the advent of every summer has been appreciably diminished through the media of intelligent legislation and practical charities. Admitting the significance and mutually corroborative nature of these circumstances, it is nevertheless evident that they fail to supply the requisite data for a numerical estimate of the prolongation of life.

Somewhat more definite results may be derived from a study of the reports of such statistical bureaus as keep reasonably accurate records. Even these figures, however, can be accepted only as more or less close approximations to the truth. The usual method of calculating the annual death-rate for a locality is easy of application and not without value, but it is at best a rough and ready device from the determinations of which deductions should be made with caution. The age constitutions of the populations of various places differ so considerably that in the comparison of two cities, such as Chicago and Vienna, for example, the story told by the conventional death-rates might easily be the reverse of true. Nevertheless, when in any particular locality, the population of which has not undergone abnormal fluctuations, the death-rate has manifested a declining tendency for a term of years, it is safe to assert that the average duration of life is increasing. These conditions are met in most of the cities of the civilized world, and it is fair to assume that in the country districts there has been a similar, though perhaps less decided, improvement.

The most important question concerning increased longevity, its distribution, remains to be considered. Is it largely confined to the extremes of life, especially the earlier, thus constituting a detriment rather than a benefit to society, or does it apply also to the productive ages? From general death-rates no answer is forthcoming. Although census statistics might be expected to solve this problem, they are unfortunately vitiated to an unknown extent by the great movements of immigration and emigration. There remains the graded mortality-table such as is used by actuaries in calculating premium-rates and which exhibits for the period to which it applies the death-rate at each age. It is obvious that two tables covering similar classes of people at different periods would show very accurately the distribution of the increased longevity already demonstrated. Two such tables now exist, thanks to the combined efforts of the British life companies, which long ago formulated their ex-

perience prior to 1863 and have recently completed a similar work for the thirty subsequent years. As was unavoidable in virtue of their origin, both tables ignore all ages below ten, at which they assume 100,000 males to be alive. Ten years later the survivors by the new table are 230 in excess of those by the old; after the lapse of twenty years, the excess is 2,077; after thirty, 3,183; after forty, 3,459; after fifty, 3,207; after sixty, 2,491; after seventy, 1,600. From these figures it is obvious that, in Great Britain at least, the prolongation of life has been characteristic of all ages except perhaps the very highest and the maximum increases chiefly affect the periods of greatest productivity. The consequent gain to society needs no demonstration. Although the tables just compared are compiled from the records of insured lives only, there is no reason to doubt that the same general causes that have so favorably affected them have been similarly operative on the rest of the community.

To the uninitiated it might seem probable that the adoption of the new table would imply cheaper insurance, but, unfortunately, such a belief would be a delusion. The cost of insurance depends on the mortality experience and business management of the company issuing the policy. Although the net premium is based on the standard table, it is usually heavily loaded for expense and various contingencies. If the company has a low death-rate and makes fortunate investments, it rapidly accumulates a surplus which may be distributed in the form of dividends to the policy holders, thus reducing the cost of their insurance. On the other hand, it may be dissipated in extravagance. In either case, it makes no difference to the insured what mortality-table is preferred by the actuaries. So far as one can judge at the present time, the hope of cheaper insurance through increased longevity is, to quote the words used by the late Senator Ingalls in another connection, merely an iridescent dream.

ENVIRONMENT AND INTESTINAL DISTURBANCE.

One of the prominent features of ordinary practice at this season is the marked tendency to the occurrence of intestinal disturbance, partly as the result of unexpected variations in the weather, partly as the result of modifications of environment incident to changes of residence after the summer.

We have learned to appreciate in recent years that intestinal digestion is much more important than gastric digestion. Complete removal of the stomach in recent surgical experience has not been followed by any serious interference with the general process of nutrition. The functional suppression of the stomach by gastro-enterostomy has been practised for several years, and not only with temporary, but permanent improvement of the health of the individual. Specialists in gastric disease assert that in not a few patients a condition of gastric anadenia, atrophy of the secretory glands of the stomach and consequent obliteration of the function of gastric digestion develop without necessarily causing any permanent impairment of the power to prepare and absorb sufficient food to support the system.

We are thus brought face to face with the fact that digestion is mainly an intestinal function. The active mucous membrane of the intestine is spread over a tube twenty-eight feet in length and is subject to many external and internal influences. One of the most important of these is adaptability to variations of temperature and of intestinal contents. This adaptability differs in degree in different persons. The intestine of each individual constantly contains a large number of micro-organisms to whose presence it has become tolerant. This microbic flora of the intestine varies very much under the varying conditions of human life. Micro-organisms that will prove not only harmless, but even beneficial for some because of certain fermentative processes adjuvant to digestion that they set up, will in others work harm by exciting irritative conditions. The intestinal flora depends not only on the actual bacteria introduced into the intestinal tract, but also upon the conditions that are maintained in it. Temperature and the form of nutritive medium are the two conditions that in the bacteriological laboratory are known most to influence microbic growth.

Slight variations of temperature may prove very important in their effects upon the multiplication of bacteria. A difference of a few degrees suffices to prevent the growth of such ordinarily virulent and active bacteria as the bacillus of anthrax or the gonococcus. Internal body temperature and notably that in the intestines is dependent on the blood-supply. This is particularly liable to variations, because the exigencies of digestion require them. Under ordinary conditions only the usual flora of the digestive tract flourish. If the surface of the body should become much cooler than normal the cutaneous capillaries, capable under ordinary condi-

tions of containing about one-fourth of the blood in the body, became contracted. The blood usually at the surface is forced to the interior of the body and finds its readiest refuge in the blood-vessels of the intestine which are easily distensible. The presence of so much blood leads to passive congestion and consequent sluggishness of the circulation. The first result of this is a lowering of the temperature of the intestines. This disturbs the equilibrium of bacterial life in the intestines.

It is well known that the growth of certain micro-organisms prevents the growth of others. The nitrifying bacteria that multiply on the surface of filter beds are the best example of this. By their presence they prevent the multiplication of pathogenic germs. When the ordinary vital conditions of the normal microbic flora of the intestines are disturbed, micro-organisms to whose irritative properties the intestines are not accustomed find a favorable opportunity to grow. Hence the intestinal disturbances that occur so frequently in variable temperatures. This is the scientific significance of the popular term "cold in the bowels."

As the disturbance of temperature conditions upsets intestinal microbic equilibrium, so also does serious interference with ordinary food conditions. Marked change in the diet, the consumption of unusual articles of food, the drinking of unaccustomed water, introduce new organisms and disturb the relations of the old to one another and to the vital resistance of the intestinal mucous cells. Practically this pathological tendency is best illustrated by what happens almost invariably in camps and for most people during the first few days at a watering place. Diarrheic conditions are almost the rule under these circumstances. Custom has established a tolerance of conditions that a change of environment makes ineffective. The treatment of the resultant intestinal disturbance must be directed to the establishment of the original conditions. The indication is not for intestinal antisepsis, at best a hopeless task, but the restoration of the previous microbic equilibrium. For this the removal of irritant material and the limitation of food, so as to cut off the supply of nutrient media for undesirable growths, are the desiderata. The prophylaxis of the annoying intestinal disturbances involves the exercise of judicious care in the selection of bland food during the first days after any alteration of environment, whether that be due to change of habitation or of temperature.

PROFESSOR VIRCHOW'S EIGHTIETH BIRTHDAY.

To the roll of famous octogenarian scientists, such as Alonzo Clark, Valentine Mott, Herbert Spencer, Lord Lister, Kölliker and Ernst Haeckel, we may add on the day of October 13th, the name of Rudolph Virchow, the father of pathology and the exponent of modern vitalism.

All scientific Europe is preparing to devote Saturday, October 12th, to celebrations and festivities in honor of the venerable but by no means antiquated professor; and so great is the enthusiasm that it has spread to the sons of science in America.

Therefore, in obedience to a spontaneous feeling of sentiment and reverence, a number of physicians have proposed to give a dinner in New York, simultaneously with their trans-Atlantic brothers, to honor the great old man.

The invitations are extended to the members of the Academy of Medicine, and Dr. Osler will be master of ceremonies; the dinner will therefore be a delightful occasion, and whether Professor Virchow be sensible or not of the kindly glow of feeling that will warm the hearts of the post-prandial speakers in his honor, the representative men in medicine who will dine together next Saturday evening, will at least be conscious of what they owe to this wonderful eighty-year-old scientist.

ECHOES AND NEWS.

NEW YORK.

St. Luke's Hospital Endowments. — St. Luke's Hospital received last week a bequest of $6,000 under the will of Mrs. Harriet B. Ranney, widow of the late Dr. Moses H. Ranney. This bequest is to be devoted to the maintenance of a bed to be known as the Dr. Moses H. Ranney Bed. An additional sum of $3,000 is to be devoted to the endowment of a bed in the same hospital to be known as the Willard M. and Julius H. Ranney Bed, in memory of her deceased sons.

New Building for St. Luke's.—The Board of Directors of St. Luke's Hospital recently held a meeting in the hospital building, on Morningside Heights, with the President, George M. Miller, in the chair. A matter of importance was the consideration by the Board of the construction of a pavilion on the northwest corner of One Hundred and Thirteenth Street and Morningside Avenue, to be connected with and form a part of the hospital, but to be devoted exclusively to private patients. Plans and specifications for the new building have been ordered. It was the opin-

ion of the directors that there is a demand for such a building that would justify the expense of building and maintaining it.

Consumptives Must Leave St. Luke's.—The Board of Directors of St. Luke's Hospital recently adopted the report of a special committee recommending the cancellation of a contract now existing between St. Luke's Hospital and the House of Rest for Consumptives. The latter is a corporation which some years ago transferred to the hospital its resources with the understanding that the hospital would thereafter care for consumptive patients.

New York Academy of Medicine.—At the opening meeting of the Academy on October 3d, Dr. A. Jacobi read an interesting historical paper on "Pediatrics in the United States before 1800." His sketches of the men who contributed to our knowledge of the diseases of children in this country were highly interesting.—Dr. Jacobi's paper constituted the Wesley M. Carpenter Lecture for 1901 and was a worthy follower of those that have preceded in this memorable series.—On Wednesday, October 9th, the Section on Otology will meet. Dr. Wendell C. Phillips will read a paper on "Symptoms Pointing to the Necessity for Operative Interference in Mastoid Suppuration," and Dr. Edwin W. Pyle will contribute a paper on "A Conservative Element in Acute Mastoid Surgery."—On Thursday, October 10th, the Section on Pediatrics will meet and a symposium on "Blood Diseases in Childhood" will be held. Dr. F. C. Wood will speak of the "Modern Technic of Blood Examinations"; Dr. G. M. Light, on the "Peculiarities of the Blood in Infancy and Childhood"; Dr. L. E. La Fétra will report on a "Case of Severe Secondary Anemia in a Child of Two Years"; Dr. C. Hermann will report on a "Case of So-called Von Jacksch Anemia"; Dr. H. Herman will report on a "Case of Leucemia of the Spleno-myelogenous Type in a Child of Eight Years." Discussion will be offered by Drs. J. Ewing, T. C. Janeway and others.

Typhoid in New York.—Cases of typhoid fever have reached high figures in New York City. The last weekly report of the Board of Health shows a decided increase in the number of new cases. One hospital has been taxed beyond its capacity, and the resources of others are under a strain to accommodate patients of this class. Yearly the number of typhoid cases increases with the coming of autumn. This year the increment is larger than the ordinary, and the accommodations at all the large hospitals are being severely taxed.

Pathological Institute Work.—Though the State Lunacy Commission, of which Dr. Frederick Peterson is the President, has selected a candidate for director for the Pathological Institute of the New York State Hospitals, his election to that position is conditional upon his passing the rigid examination mapped out under the State civil-service rules, and his name the Commission does not feel at liberty to make known for the present. A date for the examination has not yet been set, it is understood, and will not be in several weeks. Though the Pathological Institute has been without a director since Dr. Ira Van Gieson retired last spring, the routine work of the Institute has been kept up during the summer by the staff of five assistants who served under Dr. Van Gieson. When the last Legislature cut down its appropriation, the Institute curtailed expenses by giving up some of its rooms in an uptown building, and stored part of its laboratory equipment at the Manhattan State Hospital on Ward's Island, where, under the new régime, quarters will be provided for the laboratory work of the Institute.

Vaccination Law to be Urged.—The committee appointed by the County Medical Association which has been at work for the past three months inquiring into the expediency of securing a law by the next State Legislature making vaccination compulsory is almost ready to make its report. What conclusions have been reached will not be made public, however, until October 21. It is said upon good authority that, while the committee will recommend legislative action to assist in the vaccination of all persons residing within the boundaries, the word "compulsory" will be avoided as much as is possible, in order that the aggressiveness of the ignorant masses and foreign population be not aroused.

PHILADELPHIA.

Smallpox Situation More Satisfactory.—For the week ending September 28th there were 29 new cases and 3 deaths from smallpox as compared with 38 cases and 4 deaths the previous week. The Mayor has directed that the proposed annex to the Municipal Hospital, to which citizens so strongly protested, shall not be built. The State Medical Society, during its meeting here last week, passed resolutions reaffirming their belief in the efficacy of vaccination and recommending it to the public. The compulsory vaccination of school-children was also endorsed. The Committee on Hygiene of the Board of Education has ordered that teachers and other employees file within two weeks certificates showing that they have been vaccinated or have had smallpox.

Homeopathic State Medical Society.—This Society held its annual meeting in Pittsburg last week. A matter of surprise was the fact that many letters had been sent to Governor Stone by members of the profession, asking that he withhold his signature from the appropriation for the proposed State Homeopathic Insane Asylum. Dr. R. R. Mercer of Chester was elected president. The next meeting of the Society will be held in Philadelphia.

Good Results from Sanatorium.—Encouraging reports come from the consumptives at White Haven. They are now quartered in an old barn, which allows free access of air and,

fitted up as it is, makes a much more appropriate home than its name would indicate. Seventeen persons are now in the sanatorium and the improvement in their condition is very gratifying. Work on the hospital to accommodate 200 patients will soon be begun.

Philadelphia Streets.—The streets of this city are at present in an exceedingly bad condition, a local paper characterizing Philadelphia "a barricaded, disorderly city, with streetways agape and dirt everywhere." The conservative *Ledger* says: "Unclean thoroughfares have not been uncommon in the past, particularly under the present administration, but it is difficult to recall a time when the accumulation of rubbish and filth is as offensively evident as at this time, or when the city officials were as calmly indifferent in the matter of disciplining those who are responsible. One cause of the disorder is, of course, due to the tearing up of the streets by the Keystone Telephone Company to lay its conduits, and to digging the trenches by the city for the new water-mains for the better protection of buildings against fire. These works, proper in themselves, are conducted with a total disregard to the comfort or convenience of the citizens or the cleanliness of the streets." That the health of the city will suffer from this condition seems almost assured.

Notes on the State Medical Society.—President Davis made an admirable presiding officer, especially in the matter of keeping the sessions up to schedule time. Ten minutes were allowed for papers, too short a time, by the Constitution. The last ten were cut to five minutes each in order to finish on time. The special lantern demonstration was a feature of the meeting. "The Life History of the Ovary," by Dr. Clark, was a demonstration of his theory of the mechanical basis of the menopause. The ovules are pushed from the center to the periphery of the organ by a free central blood-supply. The scars left form fibrous tissue which extending outward toward the surface prevent the passage of the ovules.—The membership of the Society is 3,460, an increase of 110 during the past year. Efforts to increase it still further are to be made by a committee who will visit backward counties for the purpose of arousing greater interest in the local societies. Resolutions were passed endorsing the course of the attendants on President McKinley; reaffirming the belief of the Society in the efficiency of vaccination; and denouncing the abuse of dispensaries by people able to pay for medical attendance. The following was suggested as a remedy for the latter condition: "*Resolved*, That this joint committee recommends to our respective associations that the Legislature pass an act requiring that all persons seeking aid at dispensaries and other charitable institutions record their names and addresses, or, when unable to write, make their marks, as is customary in legal documents, in a book kept for the purpose, which shall be open to inspection by proper persons, and, if possible, inflict a penalty upon those who fraudulently receive aid."

CHICAGO.

Commencement Exercises of the Illinois Medical College.—These were held September 25th. Fourteen students received the degree of Doctor of Medicine, and one the degree of Doctor of Pharmacy.

Scarlet Fever in Evanston.—It is said that scarlet fever is quite prevalent in this city. There are at present thirty-two cases, and the health authorities are energetically fighting the disease. School attendance has been seriously interfered with, as many parents fear the disease. Milk is said to be the probable cause of the epidemic.

Appointment of Dr. Farrell.—Dr. P. J. H. Farrell has been commissioned major and surgeon and assigned to the Sixth Infantry of the Illinois National Guard.

Women Arraigned by the State Board of Health.—Seven women physicians have been arraigned by the Illinois State Board of Health for practising medicine without licenses and for advertising themselves as physicians. It is said that of these only one name appears on the physicians' register.

GENERAL.

Gift to a Physician.—Dr. A. S. Zabriskie, one of the oldest physicians of Suffern, N. Y., recently, celebrated his eighty-second birthday at his home there. He came to Suffern forty-five years ago. He was presented with a purse of $500 by his friends.

Egyptian Congress of Medicine.—The preliminary program of this Congress, to be held December 10-14, 1902, under the patronage of the Khedive, has just been received. The subjects of special interest are those diseases of distinct importance to Egyptians, notably anchylostomiasis, bilharzia, yellow fever and abscess of the liver.

Burrage Hospital in Boston.—The plans for this new hospital for the sick children of Boston have just been announced. The hospital is to be situated on Bumkin Island, in Boston Harbor, and is given for the benefit in the summer time of the poor sick children of Boston. It is intended that it shall have special reference to children who are crippled and unable to keep themselves. It is not probable that the use of the hospital will be limited to this class alone.

Zionist Father Adjudged Guilty of Manslaughter.—A member of the Christian Catholic Church in Zion was last week adjudged guilty of manslaughter by Justice Walker of Vancouver, B. C., on the charge of causing the death of his two children by failing to pro-

vide them with medical attendance, which the Judge held is one of the necessaries of life. Such necessaries the criminal code provides a father shall provide for his children.

Paris Hospital for Americans.—The project of erecting an American hospital in a suburb of Paris like the efficient English institutions of the kind was about to be abandoned when the Duchess of Marlborough made a gift of $10,000, and it seems more than likely that such a desirable institution will be founded in the near future.

Plague Reports.—The Brazilian Government has declared the city of Rio Janeiro infected with the bubonic plague. The port of the city is under suspicion. At least fifteen cases of plague have been found in Naples and vessels from that port are quarantined by the United States authorities.

Virchow Research Fund.—According to *Science,* the city of Berlin will contribute $25,000 toward the Virchow foundation for research, now being enlarged in honor of Professor Virchow's eightieth birthday.

XIIIme Congrès International de Médecine.—The General Secretary desires to inform the members of the XIIIth International Congress of Medicine that the printing and forwarding of the general volume and of the seventeen records of the Sections are now entirely finished. Any member who, by mistake, should not have received the volumes to which he is entitled is hereby requested to address the Editors of the Congress, Masson & Co., 120 Boulevard Saint Germain, Paris. After December 31, 1901, any reclamation will not be acknowledged.

Sir James Crichton Browne on the President's Case.—"I am confident I am expressing the unanimous opinion of the British medical profession," said Sir James Crichton Browne at the banquet of the Bowyers' Company in London last week, referring to a touching allusion made by the Chairman, Mr. Morgan, M.P., to the death of Mr. McKinley, "when I declare that the surgeons who attended the late President of the United States showed the utmost skill at every stage and did everything possible to alleviate the sufferings and prolong the life of their illustrious patient. American and British yachts may compete for victory, but between American and British surgeons there is no rivalry—only mutual respect and good will."

Nicholas Senn Prize Medal.—The Committee on the Senn Medal beg leave to call attention to the following conditions governing the competition for this medal for 1902:

1. A gold medal of suitable design is to be conferred upon the member of the American Medical Association who shall present the best essay upon some surgical subject.

2. This medal will be known as the Nicholas Senn Prize Medal.

3. The award will be made under the following conditions: (*a*) The name of the author of each competing essay shall be enclosed in a sealed envelope bearing a suitable motto or device, the essay itself bearing the same motto or device. The title of the successful essay and the motto or device is to be read at the meeting at which the award is made, and the corresponding envelope to be then and there opened and the name of the successful author announced. (*b*) All successful essays become the property of the Association. (*c*) The medal shall be conferred and honorable mention made of the two other essays considered worthy of this distinction, at a general meeting of the Association. (*d*) The competition is to be confined to those who at the time of entering the competition, as well as at the time of conferring the medal, shall be members of the American Medical Association. (*e*) The competition for the medal will be closed three months before the next annual meeting of the American Medical Association, and no essays will be received after March 1, 1902. Communications may be addressed to any member of the committee, consisting of the following: Dr. Herbert L. Burrell, 22 Newbury Street, Boston, Mass.; Dr. Edward Martin, 415 S. 15th Street, Philadelphia, Pa.; Dr. Charles H. Mayo, Rochester, Minn.

Yellow Fever Institute.—According to the Marine Hospital Reports, a plan for the organization of a yellow-fever institute in the United States Marine-Hospital Service, whose object will be to collect all facts concerning yellow fever, to designate the specific lines of investigation to be made, and to make the investigations, is presented by Dr. Walter Wyman, Supervising Surgeon-General of the United States Marine-Hospital Service. The members of this institute are to be the medical officers of the Service, and others specially qualified. They will be assigned for duty to one of four sections, each section having a special list of topics for consideration. Each of the four sections will be under the direction of one of the medical officers on duty in this Bureau, and said Bureau officers, with the director of the hygienic laboratory, the Surgeon-General, and a secretary, will constitute an executive board, which is to have general oversight of all the investigations. This furnishes a convenient method of administration, as the machinery of the institute will be readily operated in the Bureau, while the actual work will be carried on by members at various places. At present, the Service work on yellow fever is being conducted by a limited number of officers working on more or less independent lines. The institute provides for observation and experiment by a large number of workers in accordance with a general system—in fact, organizing and coördinating the work that has

been going on and which is to be done. The stimulus to the members will be not only the scientific interest in the subject, but the publication of their contributions in the shape of bulletins as often as it seems advisable to the board; and with the Department facilities and necessary funds for incidental expenses, it is believed that the organization will meet with a degree of success warranting its existence. Four sections are proposed—one on History and Statistics; another on Etiology, a third on Transmission, and a further one on Quarantine and Treatment. This is a desirable move and the organization of such an institute a much needed want.

National Hospital at Seattle.—Plans to establish a national hospital at Seattle, Washington, are being discussed by the Chamber of Commerce of that place as a memorial to the late President McKinley. Lieut. A. B. Wyckoff, U. S. N., retired, a member of the Chamber of Commerce, in speaking of the project, said:

"When the hospital has been built and equipped it should be placed in charge of some central and permanent authority for its government and maintenance. I would suggest that it be turned over to the General Government for the treatment of our soldiers and sailors, and the veterans of the Civil and Spanish Wars who may be suffering from serious complaints, like malaria, lung troubles, rheumatism, etc. There are homes for Grand Army men in many States, and there are hospitals for the treatment of soldiers and sailors, but none of them are located in special climates or equipped for the treatment of chronic diseases such as I have enumerated. From my wide experience in all parts of the country, I believe that no climate can be found combining the great advantages for the treatment of the above diseases superior to that of Southern California. A locality could be selected there where the atmosphere is dry and free from all malaria, in the midst of grand and engaging scenery, in the vicinity of hot mineral springs, away from the temptations of city and town, and yet where the patients could have the innocent diversions of boating, shooting, fine roads for driving and bicycling, and all kinds of out-door amusements. A warm and equable climate is necessary for the comfort and happiness of suffering soldiers and sailors, and a location in Southern California meets these conditions, as well as being the nearest point to the Philippines, where a large part of our Army and Navy will be stationed for years to come. I hope, if the Chamber of Commerce takes up the matter of a memorial hospital to our beloved President, it may do it in a definite way and along the lines of the above suggestion. Seattle has a magnanimous spirit, and will not hesitate to recommend another locality for such a purpose if it is thought to be more suitable."

Site for a New Baltimore Hospital.—The Municipal Hospital Commission of this city consummated yesterday the purchase of a site for a new hospital for infectious diseases. The land is on the Reisterstown pike, just outside the city limits. There are ten acres in the tract and the price paid was $20,000. Health Commissioner Bosley has been endeavoring for a year to make the municipal authorities realize the need of such a hospital. He believes that the new site is an admirable one. A number of handsome buildings will be erected.

Health of Philippine Army.—In speaking of conditions in the Philippines, Gen. George M. Sternberg, Surgeon-General of the United States army, who has just returned from the islands, said last week: "I was surprised at the excellence of the hospital service and the arrangements for caring for the sick and wounded. We have a department in the islands that we should be proud of. The percentage of sick remains about the same as during the early part of the campaign, namely about seven per cent. Taking into consideration what we have to contend with over there, and comparing it with the records of the civil war, it will be seen that we have made great improvements in our military hospitals. The new convalescent hospital at Santa Mesa, built of nipa, is almost perfect. The men are subject to malaria, typhoid, and dysentery for the most part. The latter is the worst. A little bubonic plague exists among the natives and Chinese, but it is not enough to occasion alarm or drive people into hysterics. I am well pleased with what I saw, and am satisfied."

Obituary.—Dr. Abram Litton, whose death was recently announced, was the oldest citizen of St. Louis, Mo., and was for fifty years a member of the faculties of Washington University and the St. Louis Medical College.

Dr. James W. Dunphy died last week from tuberculosis at the home of his parents, No. 58 Convent Avenue, New York. He had been an invalid for four years, and for the greater portion of that time had practised medicine at Saranac Lake. Dr. Dunphy was born in 1875, and at the age of nineteen was graduated from the College of Physicians and Surgeons.

Dr. E. W. McClere, of Winsted, Conn., was drowned, last Wednesday. He was thirty-five years of age, and a graduate of a New York College.

Impetigo Contagiosa.—Hodara strongly recommends touching each pustule daily or every second day, with a 50-per-cent. solution of silver nitrate. A cure is said to follow after two to four applications. For children, in case it is undesirable to trust the parents with such a strong solution, one of from 2 to 5 per cent. will suffice, but must be applied once or twice daily, and each pustule then dusted with calomel, 1.0 gram, amyl, 9.0 gram. (*Monatsh. für prakt. Dermatologie,* No. 3, Vol. xxxiii.)

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

LONDON, September 21, 1901.

THE DEATH OF PRESIDENT M'KINLEY—PROMINENT PATIENTS AND MEDICAL BULLETINS—VARIOUS METHODS OF ANNOUNCING THE DEATHS OF PRESIDENTS AND POTENTATES—SIR MORELL MACKENZIE AND THE EMPEROR FREDERICK.

THE medical profession here has fully shared in the indignation and deep sorrow universally felt by the British people at the shocking crime of which Mr. McKinley was the victim. Many of us, perhaps, were a little doubtful as to the wisdom of the early bulletins which to those who had had experience of the wayward course so often taken by abdominal wounds seemed imprudently optimistic. But we also knew that the late President was in the hands of surgeons on whose skill and judgment the most implicit reliance could be placed; and we awaited the result with confidence. The shock of the fatal issue was all the greater when it came. It has been said that the lowest depth of human misery is reached by the commander of a beaten army; but I have often thought that the position of physicians and surgeons who have to fight a losing battle against death at the bedside of one of the potentates of the world is just as unenviable. For many years one of our foremost surgeons was known to the public as "the man who killed the Emperor," and I have heard an American say in a public speech here that General Grant's end was hastened by the injudicious overfeeding forced on him by his physicians. The late Czar dismissed a physician in whom he had put his trust for years because he failed to achieve the impossible. Foolish criticisms, by no means confined to the laity, have been heard on the way in which the wound which caused the death of President Carnot was dealt with, although the case was from the first past all surgery.

Some superfine gentlemen of the medical profession here profess to feel disgust at the publication in our leading newspaper, the *Times*, of details as to the attempted rectal feeding and its consequences in the case of your late President. Such prudery in a doctor reminds one of the dainty lordling who complained to Hotspur of the soldiers who brought a slovenly unhandsome corse betwixt the wind and his nobility. The question of bulletins must always be a difficult one, and any violation of the privacy of the sick-room is of course in the highest degree indecent. But it is surely absurd to treat the case of the ruler of a powerful nation as on the level with that of an ordinary citizen. The people have, it seems to me, every right to know the truth—if not the whole truth—as to the condition of one in whose existence each of them may justly claim to have a personal interest. Presidents, princes and potentates and those about them should encourage this curiosity within reasonable limits; in the case of monarchs, at any rate, it would augur ill for the continuance of the dynasty if the people were indifferent about their illnesses. This is a truth which the Royal Family of Great Britain has never yet grasped. The late Queen, our present "most gracious" sovereign, and even the smaller fry of Royal personages have always shown a morbid dislike of publicity in regard to the ills their august flesh has from time to time been heir to. I suppose they do not care to have it known that they are subject to the common lot of humanity. Hence bulletins about them are edited with the rigor of a Russian press censor, and are carefully pruned of any expression that might be likely to convey anything but a vague general statement. Poor Lear said his hand smacked of humanity. The humblest of our Royalites would not make such an admission about any part of his sacrosanct person. As a curious instance of the courtly reticence imposed on physicians even after the death of a royal patient, I may quote a passage from the bulletin in which the death of Queen Victoria was announced. It was stated that "in the last few hours of life paresis of the pulmonary nerves set in, the heart beating steadily to the end." The exact meaning of this cryptic phrase was the subject of some discussion among members of the medical fraternity, and at last some one plucked up courage to ask one of the distinguished men who had ministered to the Queen in her last moments what the words were intended to convey. He threw the responsibility on the author of the bulletin, suggesting, however, that the phrase "paresis of the pulmonary nerves" was intended to get over the ugly term "tracheal râles." The author's own account was that it was used to cover the act of dying from what is known as paralytic filling of the lungs. So that all this mystery and diplomatic ingenuity of phrase were thought to be necessary to avoid the blasphemy of saying that the Queen had the death-rattle in her throat as she passed into the land of shadows!

In the account of the President's death given in our newspapers it was stated that the announcement of the fatal result was made by Dr. Rixey in the words "The President is dead!" There is a simple dignity about this that compares very favorably with some announcements of a similar kind that have been made in Europe. It is said that the fact of Queen Victoria having vacated the throne she had occupied so long was notified to the heir of the crown by one of the physicians as follows: "Your Majesty, Her Majesty is dead!" For grotesque incongruity this would be difficult to beat. After the close of the long agony of the Emperor Frederick of Germany, Sir Morell Mackenzie announced the fact to those about the bed with uncouth bluntness in the words "He is quite dead now." The most graceful of such announcements that I have seen is that of Dr. Barth to Madame Thiers on the death of the first President of the new French Republic: *"Madame, votre illustre mari a vécu!"*

The mention of Morell Mackenzie reminds one of a statement which recently appeared in one of your contemporaries to the effect that, owing to his conduct in connection with the case of the Emperor Frederick, he was tabooed by the medical profession here and died of a broken heart in consequence. The fact is that Morell Mackenzie had been in bad odor with his professional brethren for many years before he had anything to do with the Emperor. It would serve no useful purpose to discuss now whether they were, or were not, justified in ostracizing him; but it is only right to say that he was judged very harshly and treated as an outcast by men not one whit his superiors in professional morality and infinitely his inferiors in capacity. British doctors, being like most of their race, naturally inclined to worship at the shrine of success, and holding as an article of faith that any connection with royalty has a purifying effect on the worst social sinner, would have placed Mackenzie on a pinnacle of glory—had he succeeded. But failure meant ruin. I think, if the truth could be got at, it would be found that the profession is now ashamed of the rancor with which, at the instigation of men who owed everything to him, they pursued a man who had many fine qualities and who, had not an evil fate prevented his fulfilling the promise of his early days, would have been one of the glories of British medicine. He had bitter cause to feel the truth of the maxim "Put not thy trust in princes." He risked his reputation and his practice in trying to serve our Royal Family, for it was to ensure the Empress a larger allowance that the policy of *laissez aller* was adopted in the case of the Emperor—and when he had done what was wanted, they cast him off as a workman throws away a broken tool.

ULCERATING GONORRHEAL AORTIC ENDOCARDITIS—GASTRIC CANCER—COAGULA IN THE URINE—TRAUMATIC SCARLATINA—RACHITIC SPASMUS NUTANS—SO-CALLED FETAL RACHITIS.

Michaelis and Jacob, at the Verein für innere Medicin in Berlin, July 8, 1901, showed a heart with ulcerating gonorrheal aortic endocarditis, taken from a man who died of the disease two months after the infecting coitus and diagnosed as such during life. The confirming bacteriological and pathological considerations were the distinct and characteristic Gram's stain, the deep intracellular abode of the germ in the valve-flaps, and the characteristic growth of it only on the fixed well-known media. Since Von Leyden expounded the first definite case of this instructive condition, reports of about fifty subsequent cases have appeared in literature.

Albu showed a specimen of gastric cancer, at the pylorus, whose duration of four years had indicated benignity. In structure it was an adenocarcinoma. Contrary to the contentions of many, Albu maintains that sarcinæ occur only in benign gastric growths. This is contrary to the teachings of Strauss and others.

A. Rothschild presented specimens of coagula from the urine of a man, fifty-nine years old, who for a long time suffered from hematuria, accompanied by the presence of long coagulated masses. Their size was often that of the little finger and suggested the ureters as the seat of origin. They were rather waxy and transparent. Chemically they could not be definitely made out, excepting that they were not composed of fibrin. Late in the patient's disease an abdominal tumor manifested itself. Upon autopsy this was found to be a giant-cell sarcoma of the upper pole of the kidney. In the interstices of this sarcoma was much more of the same coagulated material as had been found in the urine. A large coagulum presented also in the ureter.

Lippmann related the history of a case of evidently traumatic scarlatina. The patient was a hale and hearty boy who during a fist-fight was struck in the cheek. That night he was overtaken with headache, chills and fever. Soon after an eruption appeared, which soon proved to be true scarlatina. The disease ran its usual course and recovery occurred only after a pronounced exfoliation. The theory of the origin of this attack is that the tonsil on the side of the face struck must have contained the streptococci and by the blow was sufficiently inflamed to set up their activity and then the scarlatina. No other possible origin of the disease was discoverable.

Stamm, at the Biologische Abtheilung des ärtzlichen Vereins, Hamburg, June 18, 1901, read a paper on the subject of spasmus nutans of children. He had himself seen 8 cases in his practice; 5 of the children were just over one year, 1 was less than a year and 2 were nearly three years old. Spasmus nutans includes the nodding, swaying or turning of the head with or without cramps and often appearing during the first year of life. The muscles of the trunk and of the extremities usually escape, but those of the eye, on the contrary, are often involved. Nystagmus was the form of this affection usually encountered by him and was of the horizontal variety, usually bilateral, occasionally unilateral. The pupillary reflexes and fundus were always normal There never were any symptoms which might point toward central nervous lesions. The nystagmus always increased in intensity if the children were at all restrained and the head movements hindered. Once in a while there appears a strange vacant fixed eye as if the child were dreaming open-eyed. The eyes are then usually turned to one side without being fixed on any special object, and meanwhile the noddings of the head are apt to be excessively severe. Loss of consciousness does not appear to have occurred. In most of the children the head movements preceded the nystagmus. In all of the cases there were present the symptoms of manifest rachitis, which always yielded to ap-

propriate treatment and left the individual in perfect health. Definite distinction must be drawn between this simple, easily cured spasmus nutans and those malignant and serious forms of spasm called salaam cramps, epileptic and eclamptic nutant spasms, due always to serious cerebral lesions, accompanied by various degrees of lumbar and extremity pareses or paralyses, loss of consciousness and commonly leaving behind them epilepsy and various degrees of idiocy or mental imperfection. Such always also have central lesions in the nervous system at their basis. Likewise in contradistinction to this rachitic must be placed the purely congenital spasm of the eyes and that acquired often during childhood, frequently accompanied by a twisted position of the head and neck and sometimes by their nodding also. The consideration of the history of these cases either as a congenital or acquired affection will establish the diagnosis. Further, the ready way in which the rachitic type yields to treatment is another means of distinction. He presented to the society a case of acquired rotatory spasm, in which the patient, a strong seven-year-old boy, had in early childhood developed a macula corneæ, and since that time had suffered from rotation of the head to one side. In discussing the various causes which in literature are assigned as the various etiologic factors (dentition, worms, various intestinal dyspepsias, trauma, etc.), Stamm was inclined to take the view of Raudnitz, who assigns it to vision and compares it to the peculiar nystagmus seen in mountain dwellers, comprising a depression of the eye toward the ground. The habits of life in these people from infancy tend always to acquire. For the true spasmus nutans rachitis is always the sole etiological factor. For the selection of certain muscles to determine the special type of nodding in various cases, doubtless we have to consider local meningeal disturbances, especially when the skull is involved in the disease to any marked degree. Therapeutically phosphorus is almost a specific.

SIMMONDS read a paper on the topic of the so-called fetal rachitis and aimed to bring out fetal life and its relations, chiefly by pure inheritance rather than by the state of parental health at the moment of conception to this disease in early infancy. In summing up the causes of rachitis, reckoning with this one must not be forgotten, for one sees cases in which the disease appears, although the food and hygienic surroundings are ideal, with the sole evident factor pure inheritance from the mother or father or both, themselves in infancy rachitic. And contrariwise one sees infants in bad surroundings, with poor food, but with a non-rachitic parental history, who do not develop the disease. It must be distinctly grasped that the question is one of truly inherited disease not of the congenital type, and at that the inheritance is rather one of disposition than of the disease itself. Concerning the absolutely congenital type of rachitis, that is, a rachitis of intra-uterine origin, he stated that he had never found one case of it, although he has had at hand a vast quantity of autopsy material, which he has diligently searched for it. He therefore stated that a really congenital rickets is probably an exceedingly rare disease. His investigations were carried to the histological standpoint also. What in earlier days was called congenital or intra-uterine rickets he has repeatedly found to be imperfections in bone development, periosteal or cartilaginous in origin, which could fittingly be called *osteogenesis imperfecta* and *chondrodystrophy*. In each the development of the bones in length is less than the normal; in the former the consistency is soft and friable and in the second it is normal. Other authorities agree in this; for example, Kaufmann distinguishes three groups of chondrodystrophia fetalis as follows: (1) Hypoplastic, in which the epiphyses remain small; (2) malacic, in which softening is present in the cartilage; (3) hypertrophic, in which a thickening of the epiphyses occurs, a very rare form. Roentgen-ray pictures were exhibited showing the hypertrophic form with its very short long bones, much bulged at the extremities, narrow pelvis and other deformities, especially bending inward of right and left femora and tibiæ at the knee. Microscopically it was shown that the lesion was purely a cartilaginous change; the cells at the epiphyseal line were not distinguishable, as they should be from the bone, and were in addition hyperplastic and hypertrophic. In the other case there was a periosteal cell-element invasion which distinguished it from the other. Under cretinism or semi-cretinism these cases could not be classed, because the typical facial expression, the characteristic development of the nasal bones, the precocious hardening of the synchondrosis spheno-occipitalis, the gross and minute pathognomonic conditions of the thyroid gland, the well-known fatty redundancy of the skin, the hypertrophy of the skin and the usual family history were all absent; in brief, not one element bespoke cretinism. Finally, therefore, the result of his careful studies up to the present point toward the rarity of truly congenital rachitis.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Fifty-first Annual Meeting, Held at Philadelphia, September 24, 25, 26, 1901.

SECOND DAY—SEPTEMBER 25TH.

(Continued from page 516.)

Bronchial Affections in Gout and Obesity.—This paper was read by Dr. J. M. Anders of Philadelphia and dealt with the various forms of bronchitis and asthma associated with obesity and the gouty state. In the obese the respiratory difficulty is often supposed to be due to mechanical effects of the fat, but in many instances there

is a low respiratory capacity and an anemia. The condition of the muscles and blood has, therefore, much to do in causing the dyspnea. A thoracic symptom of overfatness is pain, worse on exertion, in the subscapular and intrascapular muscles. A passive venous congestion of the bronchial mucosa in these cases causes a hyperemic bronchitis. There is cough aggravated by exercise and often occurring in severe paroxysms after a night's rest. Bronchial affections are more common in the anemic than in the plethoric variety of obesity. Closely connected with the last variety of bronchitis is asthma. This is probably due to the heart to some extent, but defective respiratory capacity is the greatest cause. Asthma in the corpulent is often due to gastric disturbance. The gouty state often accompanies obesity, and there is reason to think that both are due to hepatic inadequacy. This may lead to obesity owing to interference with the glycogenic function of the liver. Severe paroxysmal dyspnea in obesity is not true asthma. Erect posture relieves this condition. Asthma occurs in five per cent. of obese persons. Fifty per cent. of cases can be cured by overcoming the causative condition. Gout and obesity are closely associated. Gout independent of obesity is a potent factor in causing asthma. The attacks alternate or coincide with the attacks of gout, especially in the chronic and irregular forms. To treat successfully this form of asthma the etiological condition must be borne in mind. There are cases of the gouty state where conspicuous changes in the joints and elsewhere are lacking, but hepatic and renal inadequacy—the lithemic state—are present. In these the true cause of the asthma is often overlooked. Exacerbations in this form may occur any season of the year, as they are due to fluctuations in the uric acid present.

Pseudoleucemia, Enlargement of Liver and Spleen, Due to Lymphatic Tuberculosis.—Dr. Joseph Sailor of Philadelphia reported three cases of this condition which have come under his observation during the past six months. The cases were briefly described as follows: There is a moderate anemia, no leucocytosis, normal differential count, with gradual wasting, general anasarca, and ascites toward the last. The liver and spleen are enlarged. In some the temperature is very irregular. The superficial lymphglands are rarely enlarged, but autopsy shows tuberculous enlargement of the abdominal and mediastinal glands.

The Duration of Immunity from Diphtheria Antitoxin.—This was discussed by Dr. Henry D. Jump of Philadelphia. He quoted many series of statistics and also gave his personal experience. He concludes that immunity can be conferred, but that its duration is short—ten to twenty-one days perhaps. The expedient should be used in every family when a case is discovered.

Medical Examination as a Prerequisite to Marriage.—Dr. J. C. Bateson of Scranton read a paper in which he strongly advocated legislation requiring such examination.

At this session papers were also read by Dr. E. N. Ritter of Williamsport, on "Lay Medical Education"; Dr. John M. Batten of Downingtown on "Strength"; Dr. Louis J. Lautenbach of Philadelphia on "The Doctor's Fee: Is It Fixed and Definite?"; Dr. Linnæus Fussell of Media on "Therapeutic Notes."

Third Day—September 26th.

Address in Surgery.—Dr. James W. McFarlane of Pittsburg delivered this address, the subject of which was "The Arrest of Hemorrhage, with Especial Reference to Torsion Where Feasible to the Exclusion of All Other Methods." Dr. McFarlane advocates the use of free torsion in all cases instead of the ligature. When free torsion fails, as it will in occasional instances, limited torsion is not indicated. The ligature or some form of forcipressure is needed. The use of torsion was begun in the Western Pennsylvania Hospital in 1870. Soon the institution had a wide reputation for the rapid healing of amputation stumps. The method is now used almost exclusively in that institution. All sized arteries, from the femoral down, are treated in this way, atheroma being no contraindication. The method is superior to the ligature in point of time of appliance, it leaves no foreign body in the tissues, and no assistant, who might carry sepsis, is needed.

The Operative Treatment of Bladder Descent and Sacculation.—This was the title of a paper read by Dr. George Erety Shoemaker of Philadelphia. Reference was made to females in whom there are perineal lacerations and more or less prolapse of the uterus and bladder. The operations of curetting, amputating the cervix, repairing the cystocele and perineum, and suspending the uterus must all be done. The departure made by Dr. Shoemaker is in the management of the cystocele. The Emmett, Stoltz and other operations are too superficial. The best way is to cut out completely the anterior vaginal wall back to the areolar tissue. The bladder is peeled off from the vagina and the cut edges brought together. In 25 cases this expedient has given good results and relieved the bladder symptoms previously present.

The Present Status of the Bottini Operation.—This paper was read by Dr. Orville Horwitz of Philadelphia, who gave statistics of 834 cases by 38 operators, 36 being his own. The paper was a strong argument in favor of the Bottini operation. Horwitz believes that, if full data be obtained by a minute examination in each case, the operation is not so blind as that of tearing the prostrate out through a small hole in its capsule. Of his 36 cases there was a tendency to recurrence in only 3 instances. Constriction of the neck of the bladder is to be little feared. The principal advantages of the operation are the short time necessary, the slight shock, the rapid

convalescence, and the low mortality. It is the best radical operation yet devised.

Surgery in its Relation to Neurasthenia.—This was the subject discussed by Dr. G. D. Nutt of Williamsport. He pointed out some of the pathological states that by constant irritation produce neurasthenia. Where surgical operation is feasible, the treatment is indicated.

Rare Complications of Appendicitis, with Their Treatment.—Dr. Ernest La Place of Philadelphia read a paper on this subject. The speaker, after discussing the various infections present in appendicitis, spoke of the rare abscess formations sometimes met with. They show in various regions of the body, no pain being referred to the appendix. One case reported was a supposed empyema. Perforation of the ureter, bladder or rectum is sometimes met with. These cases show the necessity for prompt surgical intervention. In every case of appendicitis it can be said that there was a time when operation would have saved the patient's life. No one should be guilty of letting that time go by.

Radical Cure of Hernia.—The principles and detail of his method were given by Dr. Edmund Holmes of Philadelphia. In a normal person the pressure of the abdominal viscera is obliquely against the internal ring and inguinal canal. In hernia formation the pressure is straight in the line of the canal. The object of operation is not so much to close the canal as to restore the parts, so that pressure will again be indirect. For this reason not too much attention should be given to closing the external ring or bringing down the rectus muscle or diminishing the size of the cord. A new internal ring and new inguinal canal that is oblique are to be formed. The technic of the operation was given. Chromicized catgut is used, except for the skin which is united by silkworm-gut. The patient is kept four weeks in bed and an abdominal support worn for one year.

A Case of Perforating Typhoid Ulcer; Laparotomy; Recovery.—This case was reported by Dr. W. L. Rodman of Philadelphia. The patient was a girl of twelve who was suffering from a severe attack of typhoid fever. Perforation had occurred at least thirty-seven hours before operation. At the time of operation there was general peritonitis, frequent vomiting, marked tympany, and a weak pulse beyond 150 per minute. Ether was given and the abdomen opened in the middle line, as it proved, directly over the perforation. The opening was closed without paring the edges, the abdomen flushed, and drainage of gauze and a tube inserted. The operation lasted sixteen minutes, during which the patient received heroic stimulation. She finally made a perfect recovery in spite of the fact that a hemorrhage from the bowel occurred forty-eight hours after the operation. Dr. Rodman concludes that every case of perforation should have the benefit of laparotomy, even though seen some time after the accident. The case reported was thirty-seven hours after perforation, and a case of gunshot wound recovered, though operated upon fifty-one hours after the injury was received. General anesthesia can be borne in such cases. In adults he would use cocaine. Children are too nervous to give the operator needed coöperation when local anesthesia is used. An attack of sudden pain accompanied by a nervous chill the day before perforation suggested the possibility of a preperforative stage in this case; but as there are no pathognomonic signs of perforation itself, Dr. Rodman cannot see how a preperforative stage can be diagnosticated. Military surgeons look for perforations to repair themselves. It is apparently proper to decline to operate in military practice, but in civil practice it is just the opposite—as early laparotomy as shock, if present, will allow.

A Case of Ascites Due to Hepatic Cirrhosis, Treated by Transplanting the Omentum Between the Peritoneum and Abdominal Wall; Result with Autopsy Eight Months Later.—Dr. W. J. Roe of Philadelphia reported this case. Ascites was marked and intractable, the abdomen having been tapped 31 times before operation. The ascites was practically cured by operation, the patient dying from the liver condition, however. That organ was markedly cirrhotic with some fatty change also present.

Address in Obstetrics.—This was delivered by Dr. David Funk of Harrisburg. The address dealt with placenta previa, symphysiotomy, septicemia, eclampsia, and tubal gestation. In cases of placenta previa Cæsarian section is indicated in complete previa, in primiparæ when the mother is exhausted, in cases with rigid os, and in transverse positions with prolapse of the cord. Symphysiotomy is being gradually displaced in this country by Cæsarian section. Nothing new has developed in the prophylaxis of septicemia. Tubal gestation should be more often recognized and more cases saved after rupture.

Results of Operations for Cancer of the Uterus.—In this paper Dr. Charles P. Noble of Philadelphia gave statistics of various observers, including the results in 32 of his own cases. He thinks a fair conclusion from the latter is that 20 to 25 per cent. of cases are permanently cured.

Local Treatment in Gynecic Practice.—Dr. Frank C. Hammond of Philadelphia emphasized the value of local treatment in many pelvic conditions. Operation is undoubtedly avoided in many instances, but in a percentage of cases requiring operation local treatment will benefit the patient before operation. The employment of the douche, tampon, pessary, etc., has a proper place in treatment. The tampon is especially valuable in the way of medication and mechanical effect.

Instrumental Perforation of the Uterus.—A paper on this subject was read by Dr. Wilmer Krusen of Philadelphia. The ease with which a flexed or softened uterus can be perforated was emphasized. Dr. Krusen believes that no one should introduce an instrument into the uterus until he is able to diagnose the position of the

organ and discover if disease of the appendages be present. The case reported was one of perforation not recognized until omentum appeared in the vagina. Operation saved the patient.

Extra-Uterine Pregnancy.—Dr. F. P. Ball of Lock Haven reported the case of a woman who had had two extra-uterine pregnancies. Both were tubal pregnancies, one occurring three years after the other.

A Contribution to Clinical Therapeutics.—Dr. John V. Shoemaker of Philadelphia read this paper and exhibited a case of tinea versicolor.

Typhoid Fever in a Prematurely-Born Child.—This case was reported by Dr. Harry C. Westervelt of Pittsburg. On January 3, 1901, a woman in the third week of typhoid fever gave birth to a child at thirty weeks' term. High temperature in the child was noticed the following day. It fluctuated between 99 and 106° F. for some weeks, finally becoming normal February 21st. The child at birth weighed three pounds and fourteen ounces. March 21st it weighed eight pounds. September 21st the weight was over fourteen pounds. The child has also had an attack of whooping-cough.

Ruptured Tubal Gestation and the Physician.—A paper with this title was read by Dr. J. M. Fisher of Philadelphia. He stated that many cases were lost because they were not diagnosed. The knowledge of a few well-defined symptoms will prevent this error. Two points of the patient's own observation should lead one to suspect tubal gestation—disturbance of menstrual function and sterility of several years' duration following pregnancy. The symptoms of rupture are sudden, sharp abdominal pain, collapse, and acute anemia.

A New Method of Performing Nephropexy.—A paper on this subject was read by Dr. Henry D. Beyea of Philadelphia. The kidney is delivered in the usual manner and a piece of small rubber drainage tube passed around each pole of the organ, well toward the hilum, and tied externally. The tubes pass through the perinephric fascia and are thus kept in place.

Value of Tallquist Hemoglobin Scale to the General Practitioner.—Dr. M. H. Fussell of Philadelphia emphasized this point. It is accurate within 5 per cent. It is cheap and the test is rapidly made. To practitioners who say they have no time for such work, Dr. Fussell says: "Yes, it does take time, but it is worth it."

Fracture of the Neck of the Femur.—Dr. Chas. E. Thomson of Scranton reported this case. The patient was a man of sixty-two, and had gone two months without treatment. The femur was laid bare, some loose pieces of bone removed and a silver nail, 2½ inches long, driven through the trochanter and neck of the bone. There was some sinus formation afterward, but healing eventually followed. Eighteen months afterward the man walked without a cane or crutch and had 90° of painless motion.

The Pathology, Symptomatology, and Treatment of Uremia.—Dr. David Riesman of Philadelphia spoke on this subject. He referred to some nerve lesions caused by uremia—hemiplegia, aphasia, mental confusion, and insanity. Treatment is bleeding and sweating. A method of sweating which never fails is to put the patient in a bath at 110° F. for ten minutes and then in a hot pack for twenty minutes.

The Etiology of Acute Dysentery.—This was the subject of brief remarks by Dr. Simon Flexner of Philadelphia. He stated that it was definitely proven that there was a specific cause for acute dysentery. The organism resembles the typhoid-fever bacillus. An antagonistic serum can be produced.

The following papers were also presented: "Some Surprises Met with in the Practice of Obstetrics," by Dr. R. B. Ewing of West Grove; "The Value and Importance of Teaching the Fundamental Branches of Medicine from the Standpoint of Their Practical Application," by Dr. G. G. Davis of Philadelphia; "Post-Typhoidal Nephritis and Chronic Nephritis with Intercurrent Typhoid Fever," by Dr. J. E. Talley of Philadelphia; "Statistics of Typhoid Fever at the Philadelphia Hospital from 1897 to 1899," by Dr. H. B. Allyn of Philadelphia; "Amyotrophic Lateral Sclerosis," by Dr. T. L. Coley of Philadelphia.

The lantern demonstration Thursday evening was a most instructive feature. It included "The Life History of the Ovary," by Dr. J. G. Clark; "Some Lesions of Diphtheria," by Dr. R. M. Pearce; "Skiagraphy in Supposed Sprains," by Drs. C. G. Ross and M. I. Wilbert; "The Various Types of Smallpox, with Remarks on Differential Diagnosis," by Dr. Jay F. Schamburg; "Some Medical Uses of the X-Rays," by Dr. M. K. Kassabian; "The Kromskop," by Dr. F. E. Ives.

The officers chosen for the ensuing year are: President, Dr. F. P. Ball, Lockhaven; Vice-Presidents, Drs. Walter Lathrop, Hazleton; A. S. Harshberger, Lewistown; R. W. Stewart, Pittsburg; J. K. Weaver, Norristown; Secretary, Dr. C. L. Stevens, Athens; Assistant Secretary, Dr. W. B. Erdman, Macungie; Treasurer, Dr. G. B. Dunmire, Philadelphia.

The meeting adjourned to meet in 1902 at Allentown.

CHICAGO PATHOLOGICAL SOCIETY.

Stated Meeting, Held June 10, 1901.

The President, L. Hektoen, M.D., in the Chair.

Dr. Alice Hamilton presented a paper dealing with cell division in the central nervous system of the white rat before and after birth; the number and distribution of the mitoses, the period up to which they persist, and their character. Mitoses were found along the ventricular surfaces in the early stages of development, gradually ceasing here, and increasing in the outer layers, until at birth, almost all are in the outer layers. At birth mitoses are numerous and persist up to

the end of the fourth day; beyond this period no examination was made. The dividing cells are of two kinds: (1) small, devoid of visible cell body, resembling cells of the neuroglia; (2) large, with abundant cytoplasm, round, pear-shaped or spindle-shaped. These are in the gray matter of the cord and brain and correspond in measurements with the multipolar and pyramidal cells. Conclusion: In the later stages of development the offspring of the germinal cells become partially differentiated, but without losing their power to divide. The large dividing cells are, then, immature nerve cells; the small are cells of the neuroglia. In the case of the white rat, these cells retain their power of division until after the fourth day of extra-uterine life.

Dr. Wm. B. Wherry reported a case of so-called malignant (staphylococcus) carbuncle of the upper lip followed by pyemia. A barber, twenty-three years old, entered Prof. Bevan's service in the Presbyterian Hospital on February 7, 1901, and died on the 8th at 11.15 p. m. About a week before his admission he extracted a "dead hair" from his upper lip. This was followed by redness of the lip and swelling which rapidly extended to the side of the face and shoulder. He rapidly grew worse and died with all the characteristic symptoms of septicopyemia.

The postmortem examination was held twelve hours after death by Prof. Hektoen. The anatomical diagnosis is as follows: Acute, diffuse, purulent and necrotic staphylococcus inflammation of the upper lip and adjacent parts of face; multiple abscesses and hemorrhagic pneumonic areas in lungs; double fibrino-purulent pleuritis; abscess in spleen; acute splenic swelling; cloudy swelling of kidneys and liver; persistent thymus. Bacteriologically, a pure growth of the staphylococcus pyogenes aureus was isolated from the lip, heart's blood, pleural exudate, liver and spleen. Histologically, the lip shows dense cellular infiltrations with foci of necrosis containing groups of cocci which stain by Gram's method. The lung contains many pneumonic and hemorrhagic areas and mycotic emboli. The other organs show the characteristic changes of a severe infectious process. The dangers of this affection depend chiefly upon its location and the virulence of the infective agent; the prognosis is extremely grave on account of the liability to thrombosis and embolism. The treatment of the early stage which has so far given the best results is excision of the necrotic area and packing with iodoform gauze. After thrombosis and embolism have occurred, treatment seems to be hopeless.

Dr. Wm. B. Wherry read a paper on the distribution of segmentation and fragmentation in the myocardium. Twenty hearts were carefully preserved and eighteen pieces were taken from each heart. In searching for changes, the divisions into simple segmentation, and degenerative fragmentation and segmentation, made by J. B. MacCallum, were kept in mind. Degenerative fragmentation and segmentation occurred twice in the left auricle. Segmentation was distributed in the following order of frequency: left papillary muscles, wall of left ventricle, right papillary muscles, posterior surface of apex, etc. The changes in the walls practically correspond to the changes in the papillary muscles. "Diffuse" segmentation of both left papillary muscles accompanied by diastasis and displacement of the segments seems to indicate more or less general segmentation and fragmentation throughout the ventricles.

Dr. E. Friend reported a case of cystadenoma of ovary. Patient was thirty-one years old; married five years; never been pregnant; menstruation regular and painless; family history negative. About eight years ago severe pain developed in the region of the left ovary, but upon examination this was pronounced healthy. About one year ago a swelling appeared, extending from the symphysis pubis to the umbilicus, but this gave no pain until about a month ago. She then entered the hospital and at operation there was removed from the right ovary a small, multilocular cyst. The patient made an uninterrupted recovery and was discharged from the hospital cured. Adenomas develop as a result of disturbance in the formation of Pflüger's tubes in the growing ovary. Cystadenomas are simply adenomas which have undergone cystic degeneration; they consist of long, round, tortuous cavities separated from each other by connective tissue. These cavities may become obliterated entirely or partially by papilliform growths.

The present officers were re-elected for the coming year.

BOOK REVIEWS.

HEALTH AND HYGIENE FOR THE HOUSEHOLD. By JOHN JOSEPH NUTT, B.L., M.D. The Abbey Press, New York.

THIS is a small manual meant for the lay reader, containing a simple, accurate and readable exposition of the general truths of hygiene. The subjects treated are Bacteriology, Ventilation, Heat and Light, Milk, Water and Sewage, Foods and Drugs, Personal Hygiene, The Family Physician, and the Most Dangerous Classes of Diseases.

THE DISEASES OF THE RESPIRATORY ORGANS, ACUTE AND CHRONIC. By WILLIAM F. WAUGH, A.M., M.D., Professor of Practice and Clinical Medicine, Illinois Medical College, etc. G. P. Englehard & Company, Chicago.

PROFESSOR WAUGH'S little book is the last issue of the Standard Monograph Series and is arranged in two parts devoted respectively to acute and chronic affections of the respiratory organs. The purpose of the book is stated by the author in the first sentence of the preface: "It has been prepared because of the writer's belief that the treatment of acute affections of the respiratory organs has progressed far beyond that given in the text-books on practice." The program that

the author thus outlines for himself would seem to be rather extensive for so small a book. The drug treatment of respiratory diseases is very fully considered. There is, however, an abiding faith in the efficacy of drugs that is not shared by most of the medical world. Moreover, the busy practitioner would not always find it easy to decide just what is the author's favorite remedy in certain cases.

A SYSTEM OF PHYSIOLOGIC THERAPEUTICS. Edited by SOLOMON SOLIS COHEN, M.D., Vol. I., Books 1 and 2. ELECTROTHERAPY by GEORGE W. JACOBY, M.D., Consulting Neurologist to the German Hospital, New York. P. Blakiston's Son & Co., Philadelphia.

DR. COHEN here gives us the opening volumes of a new system of therapy which he is pleased to call Physiologic Therapeutics. By this he means a system of therapeutics in which drug actions play no part. In it he hopes to be able to compass the range of therapy, and, if his several contributors are as successful as Dr. Jacoby in his initial volumes, there will be every reason to believe that he has done so.

These two volumes on electrotherapy are very complete and we believe that Dr. Jacoby has given us a standard work which will be of service for many years to come.

In the first volume he considers at great length, too great it may seem, the elementary principles of electricity; these need no comment save that the applications are very clearly expressed and the point of view of the writer is that of a therapuetist rather than a physicist. This first book also has a complete description of the apparatus required for diagnostic and therapeutic purposes. It is well illustrated and will prove of service to the practitioner.

Book 2 treats of electrophysiology and electropathology, and contains as well several articles on the use of electricity in surgery and the specialties.

This work is to be warmly commended, not only for the matter contained therein, but also for its convenient and practical form.

TRANSACTIONS OF THE AMERICAN MICROSCOPICAL SOCIETY. Twenty-Third Annual Meeting, 1900. Vol. XXII. Edited by the Secretary, HENRY B. WARD, Lincoln, Nebraska.

WE have had occasion to comment on the good work done by this Society since its new birth, and the present volume bears evidence of the continued excellent character of the research carried on by members interested in the microscopical sciences.

Of the papers bearing on the medical sciences may be mentioned the Detection and Recognition of Blood by A. M. Bleile; papers on Municipal Water Supplies by H. N. Parker, G. C. Whipple, and F. S. Hallis. An addition to the Parasites of the Human Ear, by Roscoe Pound; and notes on the Parasites of Lake Fish by Henry B. Ward.

There are a number of papers of biological interest. The volume is a worthy companion to its immediate predecessors.

OPERATIVE SURGERY. By JOSEPH D. BRYANT, M.D., Professor of the Principles and Practice of Surgery, Operative and Clinical Surgery, in the University and Bellevue Medical College; Visiting Surgeon to Bellevue and St. Vincent's Hospitals, etc. Vol. II. Operations on Mouth, Nose and Esophagus, the Viscera Connected with the Peritoneum, the Thorax, and Scrotum and Penis, and Miscellaneous Operations. D. Appleton and Company, New York.

THE first volume of this hand-book deserved much more than the passing word of praise we were able to bestow upon it, and even a cursory examination of this, its complement, makes us feel equally impotent in attempting to do it justice in the brief space of the conventional review.

Its title sufficiently indicates the range of its subjects which, since it embraces the all-important and dramatic topics of genito-urinary and abdominal surgery not only is of itself intensely interesting, but gives the author opportunity for some brilliant descriptive writing which makes the volume a most fascinating one to read.

Based on the same general line of treatment of the subject matter and carried out with the same minute attention to detail which at once placed its predecessor in the front rank, this volume is essentially a guide for the practising surgeon and is perhaps too elaborate for the needs of the student, but for the actual workman its value cannot be overestimated. In addition to beautifully clear and concise descriptions of all the recognized technics, as well as of minor points that are evidently the fruit of the most exhaustive and painstaking search of the literature, the results of the author's own experience are embodied in paragraphs usually entitled "precautions" or "fallacies," which draw attention to difficulties and contingencies likely to confront the occasional operator and, unless he has been forewarned, jeopardize the result of his efforts. In the first chapter dealing with the nose, mouth and esophagus, the two most important topics, *viz.*, excision of the tongue and esophagotomy, with the various stricture operations receive ample attention, eight methods for performing the former being described. The second chapter, devoted to operations on the viscera connected with the peritoneum exclusive of gynecological work, makes the main bulk of the book and is a masterpiece of lucidity and comprehensiveness. The complicated subject of intestinal anastomosis is well-handled and the frequently very intricate manipulations necessary in some of the operations are made clear and intelligible while special subjects like appendicitis receive adequate and thoughtful consideration. The section on hernia is remarkably thorough, and both in point of writing and illustration is one of the best in the book. Cushing's method of herniotomy under lo-

cal anesthesia is described, although the author is non-committal as to his own opinion of the value of the procedure. The chapter on the anus and rectum is unusually full, though we miss the description of Maunsell's useful method of telescopic proctectomy. The next section treats of the neck and thorax, the critical operation of bronchotomy in its various forms being adequately described as well as the technic of intubation. The final chapters on the genito-urinary tract and on various unclassified operations, such as the suture of ununited fractures and excision of the cervical sympathetic deserve nothing but praise and reflect the most modern teaching.

From a pictorial standpoint the book is in a class by itself, for in addition to their great profusion the illustrations are thoughtfully chosen and for the most part beautifully executed. The diagrams are really enlightening and the perspective drawings accurate, while the full-page photographs of the instrumentarium required for each type of operation are both instructive and practically useful. As it stands in its completed form the work is one that American surgery may well be proud of, and it will undoubtedly take precedence over all others of its kind for many years and be an enduring monument to the skill and learning of its author.

LECTURES ON THE HISTORY OF PHYSIOLOGY DURING THE SIXTEENTH, SEVENTEENTH AND EIGHTEENTH CENTURIES. By SIR M. FOSTER, K.C.B., M.P., M.D., D.C.L., Sec. R.S., Professor of Physiology in the University of Cambridge, and Fellow of Trinity College, Cambridge. University Press, Cambridge. The Macmillan Company, New York; $2.25.

"To Dr. L. C. Lane of San Francisco and to any other friends of that new world, the story of whose life is as yet so short, but must in time be so great, I offer as a token of my friendship this fragment of the story of the old world's life." This is the graceful and fitting dedication to this volume making up the "Lane Lectures" delivered by Sir Michael Foster at the Cooper Medical College in San Francisco in 1900.

It is a pleasing thought that so excellent an idea as the gathering together somewhat of the lives of the workers in physiology in these early centuries should have been chosen by one of the acknowledged masters of physiological thought and the medical reader is to be congratulated that so able and interesting a book is available.

The opening chapter on Vesalius, his Forerunners and Followers, sketches in a pleasing manner the state of physiological knowledge of the time. This is followed by an account of Harvey and his work; Borelli and the influence of the newer physics; Malpighi and his histological researches and their influence on physiological teaching. Van Helmholtz and the rise of Chemical Physiology make a fifth chapter, and following this in order are chapters on Sylvius, The Physiology of Respiration in the Seventeenth Century, The Physiology of Digestion in the Eighteenth Century, The Rise of the Modern Doctrines of Respiration, Black, Priestley, Lavoisier, and the Older Doctrines of the Nervous System. Such is the brief skeleton of the contents of this excellent series of lectures. We recommend them most heartily to our readers.

ATLAS AND EPITOME OF OPHTHALMOSCOPY AND OPHTHALMOSCOPIC DIAGNOSIS. By PROFESSOR DR. O. HAAB, Director of the Eye Clinic in Zurich. From the Third Revised and Enlarged German Edition. Edited by GEO. E. DE SCHWEINITZ, Professor of Ophthalmology, Jefferson Medical College, Philadelphia. W. B. Saunders & Co., Philadelphia and London.

THE intimate relationship existing between the eye grounds and various systemic conditions is being more and more widely recognized, and while it is true that a certain amount of practice is necessary before the ophthalmoscope can be made to yield satisfactory information the number of general practitioners anxious to avail themselves of this aid to diagnosis is constantly increasing. But even after the initial difficulties of technic in the use of the instrument have been mastered, the question of the interpretation of the things seen remains to be solved, and, unless the observer has had wide experience in this line of work, an atlas is indispensable. Heretofore, however, such works have been out of reach of the profession in general owing to their extremely high price, but with the appearance of this addition to the excellent series of hand atlases, of which it makes part, this difficulty no longer exists. Like the other members of the series, this volume is a marvel of beauty, and all the ordinary lesions and many of the rare ones are depicted with a fidelity of form and color that leaves nothing to be desired. In addition to the plates reproducing the ophthalmoscopic images, there is a small number of colored lithographs of microscopic sections, showing the minute changes attendant on such lesions as glaucomatous cupping, choked disk, etc.

The last plate is a simple pupillometer, consisting of a series of black disks each varying by half a millimeter and intended to be removed from the volume for use, while in an introduction of about eighty pages, the more important principles involved in ophthalmoscopy are laid down.

DIE SERUM, BAKTERIENTOXIN UND ORGAN PRAPARATE. By Dr. pharm. MAX V. WALDHEIM. H. Hartleben, Vienna, Pest, Prague.

THE attempt to bring together and to arrange into a single volume the scattered papers and experiments bearing on the therapy of the serums, bacterial toxins and organic extracts, has resulted in this excellent small volume.

It is unnecessary to detail the subjects treated as the title is sufficiently explicit, but it is to be said that the work has been well done and that for a beginner more particularly much information may be gathered by little effort.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXIX. NEW YORK, SATURDAY, OCTOBER 12, 1901. NO. 15.

SPECIAL ARTICLE.

THE ENDOWMENT OF MEDICINE.[1]

BY MALCOLM MORRIS, F.R.C.S.,
OF LONDON, ENGLAND.

MR. CARNEGIE some years ago said that the millionaire who dies rich deserves a dishonorable grave and he appears to be earnestly striving to avert such a calamity from himself. His example is being imitated by others who find what Rabelais calls the "pecuniary imposthume" so burdensome as to call for evacuation. Millionaires are vying with each other in giving of their abundance for public purposes. The names of Lord Iveagh, Mr. A. L. Jones, and Mr. Yates Thompson in England, and Mr. Rockefeller, the Vanderbilts, Mr. J. Pierpont Morgan, Mr. Johns Hopkins and many others in the United States will live not only in the mouths of men but in the magnificent foundations which medical science owes to their enlightened liberality.

All here will doubtless agree with President Eliot of Harvard who in announcing the recent gift of a million dollars to the medical department of Harvard University said: "There is no department of the University to which a great gift of this sort could be made with a greater hope of an abundant return. The progress of medicine and surgery during the last twenty years is simply amazing. The triumphs of the physician and surgeon over death and disease are unparalleled in the whole history of the world, but we have as much and more to look forward to and I know no department of scientific research from which greater hope can be entertained than the department of applied biology. Moreover this great gift comes as a reward to one of the most laborious and enthusiastic and hopeful of all the faculties of the University—the faculty of medicine." The wealthy philanthropist could find no better way of using his money for the benefit of mankind than the endowment of medical research; for it is in the growth of knowledge relating to living matter that lie the best hopes for the future of the human race. But the knowledge gained in the laboratory will be, as Falstaff says, like a hoard of gold kept by a devil, unless it is set in action and used for the prevention of disease and the relief of suffering. The endowment of research therefore cannot fulfil the purpose which is intended unless it is supplemented by the provision of means for the practical application of its results. And among the means to this necessary end the chief is the proper education of those who have to apply the results of research.

[1] Address delivered before Johns Hopkins University, Oct., 1901.

Medical education might at first sight appear to concern only those who wish to practise the art of healing. But in reality it concerns even more closely the people at large on whom they will practise their art. If physicians and surgeons are imperfectly equipped for the important functions which they discharge towards the community and the individuals who compose it, both the community and individuals must suffer. Again, if there be not an adequate supply of doctors a large proportion of the victims of illness and accident must necessarily go unrelieved. These are plain facts, so obvious that they do not need to be insisted upon.

It may be said there is no fear of a dearth of doctors or of medical schools and it may be admitted that at the present moment there is in most civilized countries a superfluity of doctors and no want of medical schools. Certainly in the United States you are abundantly supplied with such institutions. Nevertheless it does not need the gift of prophecy to foresee that the time is not far distant when the profession so far from being overcrowded will, unless means are found to prevent such a consummation, tend to dwindle in numbers and also in usefulness while medical schools will undergo a process of deliquescence. It is not that medicine will cease to fascinate minds thirsting with the divine love of knowledge, or to offer a career in which any one of fair ability who is willing to work may find a livelihood. The cause is a purely economic one. Medical education is becoming so expensive that, unless its costliness can be kept down by endowment, it must tend more and more to become a luxury reserved for the rich.

One has only to look backward a very few years to appreciate the prodigious change which has come over the whole system of medical education. When I began the study of medicine thirty-five years ago the arrangements for teaching were of a simplicity that to us in these days seems quite primitive. Except the rooms set apart for practical anatomy and practical chemistry there was nothing whatever in the shape of a laboratory. Histology, such as it was, was taught with the help of a few cheap microscopes down which the more earnest of the students strove for the privilege of peeping from time to time. At the distribution of prizes in one of the leading medical schools of London in 1870 the late Professor Huxley, then examiner at the University of London where the standard was incomparably higher than anywhere else in Europe, complained that even the best students had the most misty ideas on the elementary facts of physiology, because they had not been taught it as they were taught anatomy, that is to say by

direct observation of phenomena and contact with the facts of Nature. But how could they have been so taught when there was, I believe, only one physiological laboratory at the time in London? That laboratory, it may be added, though in a spiritual sense illuminated by the brilliant genius of the men who worked in it, in regard to apparatus and even furniture, it reflected the poverty which was the portion of scientific teaching in those days. And such as it was only a select few of the students took advantage of the opportunities which it offered. Pathological laboratories did not exist and clinical laboratories were not even among the dreams of the future. That this state of things was not confined to London may be gathered from the interesting reminiscences contributed by Sir William Gairdner to the recently published "Book of the Jubilee in Commemoration of the Ninth Jubilee of the University of Glasgow 1451-1901." The distinguished Emeritus Professor of Medicine in the University on the Clyde there says that in "the Sixties the prevailing conception of the requirements of a professoriate were a lecture room (with a chair, of course!), a retiring room, and a few other unconsidered trifles in the way of blackboards, chalk, diagrams, etc."

Now we have laboratories not only of anatomy, physiology and chemistry but of pathology, bacteriology, hygiene, pharmacy, and pharmacology, to say nothing of departments for the practical teaching of obstetrics, surgery and medicine. Then there are the clinical laboratories attached to the various services in hospitals. And in this matter scientific teaching is like the daughter of the horse-leech and is ever crying "give, give!" Now even for an examination apparatus of various kinds is required.

In the old days the medical student got his knowledge from lectures supplemented by the reading of text-books; now he gets it at first hand in the laboratory. This is as it should be. But modern laboratories absorb more money than the most eager alchemist ever threw into the flames of his furnace in the search for the philosophic stone. Vast sums are needed to build and equip and maintain them. Then there must be teachers, and these must be men who give their life to scientific work and who therefore require to be paid at a rate that shall at least keep their mind free from sordid cares if it does not recompense them for the sacrifice of the chances of practice. Moreover they must have assistants, and these also must be paid on a scale sufficient to attract men of the highest ability. Altogether therefore the laboratories absolutely necessary nowadays for the adequate training of practitioners of medicine, are so costly as to make it impossible to maintain them at a proper level of efficiency without external aid.

It may be said that the money should be supplied by the students. The cost of a medical education is already so heavy as to debar many otherwise fitted to adorn the profession from entering it; and as medical science expands education must necessarily become more and more expensive. In some of our London medical schools the funds are to a large extent supplied by the medical staff of the hospital to which they are attached. It is obviously unfair however that this burden should be borne by men who give their services to the hospital without remuneration; and it is clear that, as the burden tends to become heavier, the limit of endurance will sooner or later be reached. On the other hand if the students' fees are to be increased to the degree necessary to support the school, there will very soon be no school to support. It is clear therefore that unless some *deus ex machinâ* comes to the rescue, our medical schools must collapse.

It may be said that there are too many medical schools and that some of them might without disadvantage be allowed to die a natural death. Even if this be admitted, the fact remains that, if the supply of doctors is to be proportionate to the needs of the population, the means of an adequate education must be within their reach. For this purpose there must always be a considerable number of medical schools, and it is self evident that these schools will, under the conditions of modern scientific development, never be self supporting.

The only solution of the problem lies in endowment; and for this we must look to the State or to the pious founder. I read not long ago in a leading medical journal of this country that a distinguished New York physician and teacher had said: "I hold that the State ought to furnish sufficient funds for the adequate and thorough instruction of all pupils in every medical institution already legally organized, and for such others as the increase of population may cause to be established under the regulation of the State." This would certainly be a "large order" for the State to undertake, and I think the taxpayer would be justified in a revolt against such a demand. But that the State should contribute towards the provision of a sound training for a profession whose services it is likely to find increasingly necessary seems to me an incontrovertible proposition. In Germany, in France, in Italy, and indeed in every country in Europe except England, the State takes upon itself a large share of the burden of medical education. And what is the result? England which not long ago was in the van of medical progress is now slowly but surely falling to the rear. There is far more than the question of national pride involved in this scientific retrogression. The want of opportunities for acquiring the skill and knowledge needed for the successful practice of medicine must in no long time have an unfavorable effect on the physical well-being of the nation; it is conceivable that it might even help to bring about its downfall.

It is on this ground that the State may fairly be asked to include liberal grants in aid of medical education in its Budgets. But we want the pious

founder too. While we rejoice to see the stately Temples of Science which have arisen in Liverpool, in New York, in Philadelphia, in San Francisco, here in Baltimore—where if one wishes to see a monument of enlightened munificence he need only look around, we appeal to any millionaires who may be looking for a worthy object of benefaction to think of the claims of medical education. There could surely be no way of applying wealth more useful to mankind than to help to secure the completest possible training for those who are to be the guardians of the public health.

THE INFLUENCE OF THE COLORADO CLIMATE UPON PULMONARY HEMORRHAGES.[1]

BY S. G. BONNEY, A.M., M.D.,
OF DENVER, COLO.;
PROFESSOR OF MEDICINE, UNIVERSITY OF DENVER; VISITING PHYSICIAN TO ST. LUKE'S HOSPITAL.

A COMPLETE discussion of this subject should include the preliminary introduction of certain physiological considerations followed by the collaboration *en masse* of clinical facts.

The physiological interest centers chiefly in the respiratory and circulatory changes produced by the diminished barometric pressure. Relative to this in health, much valuable information has already been advanced. It seems sufficient for present purposes to call attention briefly to the increase in the depth and frequency of the respirations and in the rate and vigor of the heart contractions. From this there results a considerable degree of vesicle dilation, increased chest expansion, greater lung capacity, together with an acceleration of the blood-flow and an equalizing of the circulation throughout the body. The tendency to local stasis or capillary congestion in the lungs is thus avoided.

The peculiar changes in the blood itself incident to the altitude consist in an increase of the hemoglobin and in the number of red blood-cells. It is reasonable to suppose by virtue of these influences that the tendency to pulmonary hemorrhage in high altitude should be distinctly lessened in cases judiciously selected with reference to other considerations. It remains for the correctness of this to be demonstrated ultimately by the established facts of clinical experience, and such shall be the scope of this paper.

In presenting the result of my personal observations it is my desire to refute any prevailing opinion that elevated regions are unsuited for hemorrhages in general. It is my conviction, however, that hemorrhages *per se* constitute neither an indication nor a contra-indication for moderate altitudes. The hemorrhage, let it be remembered, is but one of many outward manifestations of the disease, occurring at any stage of the infectious process due to a variety of causes with widely differing pathological conditions, associated with all manner of concomitant symptoms, and representing but a single component and perhaps comparatively unimportant part of the clinical picture as a whole.

While it will be seen that hemorrhage cases with certain modifications have done exceedingly well in Colorado, it is insisted, nevertheless, that the choice of climate must be made with reference to *all* the several phases and conditions, without especial attention to hemorrhage itself, save under the specific circumstances to be hereinafter described.

My observations are derived from my private work in Colorado during a residence of nine years. I have selected from my list of recorded patients a series of nine hundred cases *seriatim*, which may be said to fairly well represent the character of cases sent to Colorado taken as they come, and who have remained sufficiently long under observation to permit at least approximate conclusions.

I make no effort at this time to classify the cases with reference to physical conditions and prognosis at time of arrival, as such distinctions do not appear pertinent to this inquiry. It should be said, however, that the very incipient cases were but seldom observed and that the great majority belonged to the category of advanced infection. The patients required no admission blanks to gain entrance to Colorado and many are thus included with a prognosis utterly hopeless from the beginning. I have thought it best to embrace even these in the list in order to secure an authentic and established basis upon which to compute further statistics. As briefly illustrative of the general character of the cases I will refer to one of my previous papers,[1] in which it is stated that "out of five hundred and forty-six cases, seventy-one per cent. of the patients arrived in the State with distinct evidence of tubercular infection in each lung and with a total average period of delay following the definite onset of the disease before arrival of over eighteen months, affording abundant opportunity for advanced pulmonary and constitutional impairment."

With many of the cases it has been possible to maintain for prolonged periods a strict supervision of daily life and habits fully equal to that observed in any well-regulated sanatorium. A suitable régime has been quite as closely adhered to here as is possible in the latter institutions, but a tremendous handicap has been experienced from the advanced nature of the cases as a class. A very large number of the list, however, despite extensive infection and doubtful or grave prognosis, I have not been permitted to observe under the best conditions of life or management on account of peculiarity of temperament, habits of dissipation, domestic relations and financial distress. Many have been compelled to practise the strictest economy, others to work daily. Some

[1] Read before the American Climatological Association, at Niagara Falls, June 5, 1901.

[1] "Observations on Pulmonary Tuberculosis in Colorado," Boston Medical and Surgical Journal, September 16, 1897.

have been burdened with family responsibilities and still others have indulged in the most reckless dissipation. It is apparent that this series as a whole comprises an exceedingly heterogeneous class and differs widely from the selected cases representative of sanatorium results. The cases have been conscientiously recorded and the computation of the following statistics has been conducted personally and with as much care and pains as possible. With reference to results obtained I have made two broad classifications, *i. e.*, those who have shown improvement in Colorado and those who have grown worse or died. By improvement I refer to a material lessening of the activity of the tuberculous process as disclosed by physical signs, diminution of cough and expectoration, also of pulse and temperature, with increase of appetite, digestion and weight. It is hardly necessary here to further classify the various stages of arrest. I am frank to admit that I am reporting as improved several who are now dead, but had exhibited a progressive and material gain until suddenly overcome by intercurrent disease, accident or other extraneous and direct causes.

On the other hand several are reported as not improved whose loss following an initial gain is easily attributed to a return East, resumption of work, disobedience of instructions or other indiscretions. In a work of this kind it is recognized that everything depends upon the integrity and authenticity of reports and I have thus endeavored as far as possible to eliminate sources of error.

Number of cases improved.....618
Number grown worse or dead.....284
Percentage of cases improved.....68.5

Generally speaking over two-thirds of the cases coming to Colorado, independent of the question of hemorrhage, but in all stages of advanced infection, may be expected to gain. This is certainly a very large proportion in view of the indiscriminate character of the cases, but furnishes a basis from which to draw further conclusions relative to hemorrhage.

Four hundred and fifty-seven cases are found to have had a hemorrhage sometime during the course of the disease; of these 308, or 67.8 per cent., are reported as improved. It then appears that about one-half of the entire number are hemorrhagic cases, and approximately the same proportion have improved in Colorado as the non-hemorrhagic, each class having about the same percentage of improvement as the entire list. This comparison in itself fails to indicate any specific influence of the climate upon hemorrhage cases in general.

Much of interest and value attaches to the time of hemorrhage relative to residence in Colorado. One hundred and seventy-five cases present the history of hemorrhage as the first symptom distinctly referable to the disease or as supervening immediately upon appearance of cough and beginning loss of weight. Thus about twenty per cent. of all the cases of consumption are found to experience a hemorrhagic onset of the affection. In these the bleeding almost necessarily took place before the development of any very extensive destructive change in the lung. These cases have usually sought climatic relief early and it is in precisely such conditions that an equalizing of the circulation by high altitude should be attended by the best results. It is not surprising, therefore, to find that 127, or over 72 per cent., have done well.

Three hundred and eighty-six, or over 82 per cent., of the hemorrhage cases occurred before arrival in the State, including those with hemorrhagic onset. Of these 253 are reported as improved, establishing a percentage of 65½, which is quite up to previous standards.

Of the 386 with hemorrhage before arrival only 97, or 1 in 4, have suffered subsequent recurrence in Colorado. Among those who did experience a recurrence, but 59 are found to have done well, effecting a percentage of 60. On the other hand, out of 289 with previous hemorrhage and no recurrence 201, or 70 per cent., have shown improvement.

The logical deduction is that among the comparatively small number who do have a recurrence in Colorado of their previous hemorrhage, the chances for recovery are somewhat below the average, while those who do not experience such a return are correspondingly favored with better than average prospects.

It must be remembered that among those with previous hemorrhage and subsequent recurrence, many are included who had a distinct hemorrhagic onset and, although without extensive destruction of lung tissue, had experienced nevertheless a considerable circulatory disturbance from slight causes and who might well be expected early upon arrival, with the usual nervous temperament and erethetic habit common to such cases, to suffer a temporary return.

It is further of interest to note that of the ninety-seven recurrences thirty-four were in individuals who had experienced a hemorrhage within two or three weeks before arrival and in whom it is reasonable to suppose the direct results had not been fully overcome. In fact nearly half of those had their hemorrhage on the train or at the time of starting. Twenty-two of the recurrent hemorrhages in Colorado were in these people in whom the bleeding took place immediately before arrival and the recurrence within a very few days thereafter. It is obvious that such cases should not be embraced among hemorrhages in Colorado, as the specific cause was put in operation before arrival. Should these be excluded, and rightly so, the percentage of recurrences in Colorado would be materially diminished.

On the other hand 47 cases are found to have bled more or less profusely, and often repeatedly so, within one or two weeks before arrival, yet have never suffered a return since residing in the higher altitude.

Seventy-one experienced their first hemorrhage

in Colorado. Of these 33, or 46.4 per cent., have done well. An explanation of the small percentage of improvement is found in the fact that 40 of these were associated with very extensive and advanced infection, such conditions being present as would be likely to occasion hemorrhage anywhere. Thirty-one took place in the midst of a general gain, but in these without exception a distinct external cause could be assigned, and usually improvement was later continued.

Taken altogether, including the initial and the recurrent hemorrhages, 168 have bled in Colorado, 68 very shortly after arrival usually preceded by others immediately before coming. Of the remaining 100 cases 48 are found to have occurred as a result of accident or great indiscretion. The great majority of the balance, 52, took place in the midst of a general decline associated with more or less extensive cavity formation, syphilis or kidney disease, entailing a poor prognosis in any locality.

Of the 168 cases there were 58 easily recognized cavities, nearly one-third of the whole number arriving as advanced cases and usually with a history of a previous attack.

The character of the hemorrhage has been severe and copious in 65 instances, moderate in 103. As a general rule, they are stated to have been considerably more severe and harder to control than any previous attack at or near sea level. Four have been instantly fatal. In 13 death has resulted in a very few days. Twenty-one have survived but one or two weeks. The remainder rallied sufficiently to continue the struggle, only finally in some instances to succumb as a remote result of the loss entailed by the hemorrhage. Many have suffered no permanent ill effects, often rallying from the very alarming attacks and some have exhibited most remarkable improvement following it. Of the latter class fourteen are conspicuous examples.

My conclusions are:

1. That hemorrhage by itself, save with few exceptions, furnishes no criterion upon which to base a choice of climate, the indications for high altitude in uncomplicated and in not too-far-advanced cases being highly imperative independent of this single manifestation.

2. That an exceedingly small proportion of recurrences may be expected in Colorado, although not necessarily reflecting accurately the degree of ultimate improvement secured.

3. That recurrences are more likely to result, and that quickly, in those cases with hemorrhage immediately preceding arrival, and hence the wisdom of a short delay following the hemorrhage before leaving home and unusual precautions as regards rest upon arrival.

4. That primary hemorrhages are comparatively rare in Colorado and usually take place incident to a rapid progressive destructive change in cases already with hopeless prognosis, or as a natural result of some external assignable cause, which under proper régime could be avoided.

5. That hemorrhage, while less likely to occur in Colorado than at sea level, is nevertheless, as a general rule, more severe and associated with greater shock.

6. That the avoidance of hemorrhage, particularly in the early months of Colorado life, demands a most rigid compliance with detailed instructions.

THE TUBERCULOSIS QUESTION.*

BY H. ARROWSMITH, M.D.,
OF BROOKLYN, NEW YORK.

AN adequate consideration of the present status of the tuberculosis question is not to be thought of in the limits of a paper as condensed and superficial as my portion of time allows, and, although the subject has been exhaustively handled by more capable pens than mine, it has seemed to me that there are some points in regard to this great scourge of humanity that cannot be too often repeated or too forcibly impressed on our minds. Even at the present day the laity, and too often the profession, at the dreaded name of consumption are prone to fold their hands and wait for the end, or to perfunctorily commence the administration of some time-(dis)honored remedies and then resign themselves to the will of heaven.

It is fair to assume that to-day probably no one questions the fact that tuberculosis is acquired by the entrance into the organism of the specific germ, which may take place by ingestion, inhalation and inoculation, and probably in this order of frequency. Direct transmission of tuberculosis from parent to offspring has been demonstrated in some 18 instances, but it seems scarcely likely that it occurs sufficiently often to be of practical importance to us.

Bacilli have been found in seminal fluid in several instances, and Goldschmidt has injected weak suspensions of the germ into the vagina of a rabbit immediately after coitus and shortly after a litter had been dropped. On the sixth day, before the embryo had become attached to the uterine wall, more than 500 sections were made of the uterus and embryo. The bacilli were found in every instance inside the cells of the embryo and none were discovered in the uterus or vagina. This is, to say the least, suggestive.

Most cases of direct transmission have been from the maternal side. Armanni succeeded in infecting a guinea-pig with typical tuberculosis by inoculation with the organs of a stillborn child of a tuberculous mother. Lehmann reports the case of an infant of a tuberculous woman dying four days after birth with tubercles containing bacilli in the spleen, lungs and liver. Tuberculosis of the placenta has been studied by Schmorl and Kockel. In three cases observed, bacilli were found in the placenta, but in only one of them in the organs of the fetus. Bar and Renon demonstrated bacilli in the umbilical veins of children born of tuberculous mothers.

* Read before the Associated Physicians of Long Island, Sag Harbor, L. I., June 15, 1901.

Roger and Garnier have observed bacilli in the milk of a phthisical nursing woman. Animals injected with it died of general tuberculosis. Her child, after nursing only two days, died in six weeks with tubercles in the liver, spleen, kidneys and mesenteric glands. There was no appreciable lesion of the breasts.

There has been a great diversity of opinion as to the exact influence of heredity in relation to the development of tuberculosis. Much importance has always attached to the transmission from parent to offspring of predisposition to tuberculous disease. To quote Billings: "In most of the so-called hereditary diseases, that which is transmitted from parent to child is not the disease itself nor its direct specific cause, but some peculiarity of tissues or organs which in the course of development, either makes the person peculiarly susceptible to causes of disease acting from without, or produces disorder itself by excess or defect of structure or function of some particular part. In scrofula and in consumption and other forms of tuberculosis, the specific germ is very rarely, if ever, transmitted, inheritance giving only a special susceptibility to its action."

In an editorial in the *Journal of the American Medical Association,* February 16, 1901, the following statement is made: "The English colony in Madeira was composed almost entirely of persons with tuberculosis, seeking the benefit of its climate. It has numbered about 600 souls, and yet during the entire nineteenth century, only one of the descendants has died of pulmonary tuberculosis, possibly acquired during a residence of several years abroad."

On the other hand, the statistics of the Mutual Life Insurance Company of New York indicate an increased liability to phthisis, where there is a family history of tuberculosis, which may be estimated at 30 per cent., and Squire's researches give practically the same results.

Tuberculosis has been acquired by inoculation in a variety of ways, by tattooing, by the bites of insects, by ritual circumcision, by coitus, by handling infected clothing and utensils from tuberculous patients and by other forms of contact with them. Tuberculosis of the cervical glands has been caused by infection through carious teeth.

As to the rôle of the tonsils, faucial and pharyngeal, as foci of infection, there is great uncertainty. Many authors claim to have seen latent or larval tuberculosis of these organs many times, while other equally careful observers deny their assertions. Goodale found in some experiments that methyl blue rubbed into the crypts of the tonsils was absorbed and carried into the deeper structures, as evidenced by microscopical examination after removal. Wright has recently made some investigations which corroborate these findings, but, curiously enough, in a few instances he found that while these structures can be penetrated readily by inorganic substances, the cocci which were numerous in the crypts could never be found below the mucous membrane. This certainly appears to demonstrate the innate resistance of living tissue to pathogenic germs.

In the matter of infection by inhalation, we have been taught to dread sputum which has been dried and disseminated as dust, but that there is palpable danger in too intimate contact with tuberculous patients, the researches of Flügge, Goldie and others have shown. Plates held before the mouths of patients while coughing, sneezing and speaking have shown the bacillus in notable numbers and they have also remained suspended in the air for considerable time.

The method of infection which is alone capable of adequately explaining all the phenomena is that of ingestion—perhaps, in some cases, a mixture of inhalation and ingestion. A current of air laden with solid particles will naturally deposit them on the first surface upon which it impinges, particularly if that surface happens to be moist. As few people breathe continuously through their noses, a large proportion of the matters suspended in the inspired air is naturally deposited on the posterior wall of the pharynx and thence inevitably carried downward by the act of swallowing. Under normal conditions, the gastric juice has decided bactericidal power, but may not the gastric disturbances which almost invariably antedate a tuberculosis furnish the opportunity for the bacillus to enter the system by impairing the protective capacity of the stomach secretions?

Once having entered the intestines, having been absorbed by the lacteals and conveyed to the thoracic duct, the bacillus is easily disseminated to all parts of the body, and surely all the clinical phenomena of bone, joint, meningeal and visceral tuberculosis find here a logical and satisfactory explanation which is possessed by no other mode of infection hitherto suggested. On this basis it is easy to comprehend how infected foodstuffs may be sources of the gravest peril. The warning is obvious of the risk run by the use of food products which are displayed on the streets of our cities, exposed to the bacillus-laden dust, particularly those which are destined to be eaten uncooked, as fruits and green vegetables. Of late there has been some doubt expressed as to whether the ingestion of the meat from tuberculous animals is really as dangerous as we have supposed. It is claimed that the ordinary processes of cooking render it fairly safe—much more so than raw milk. The comparative immunity of the Hebrew race is said, however, to be largely due to the rigid inspection of the meat used by them. After careful preparation good food is probably often spoiled by contamination by flies which have been in contact with tuberculous excreta.

The sum of our knowledge relative to the antecedent causes of phthisis now seems to be that, given the favorable soil, however produced, and the proper exposure, tuberculosis will result. Precisely what the proper soil is must remain largely a matter of speculation. That a predisposition is

often inherited is unquestionable; that it is, perhaps, as frequently acquired is equally so.

Robin and Binet[1] found in 1,300 tests of the chemistry of respiration in 392 persons, that in all but 8 per cent. of the 162 tuberculous patients included, the exchanges of gases in respiration were far more active than in healthy persons. The results of their researches are tabulated and the averages show that in chronic tuberculosis the carbon dioxide exhaled per minute and per kilogram of the body weight is in women 86 per cent. more than in normal conditions, and in men, 64 per cent. The total oxygen consumed increases in women by 100.5 per cent. and in men by 70 per cent. The oxygen not used in producing carbon dioxide and which is absorbed by the tissues increases in women by 162.8 per cent., and in men by 94.8 per cent. The lung ventilation increases in women by 110 per cent. and in men by 80.5 per cent. As the disease progresses and the lung capacity and the proportion of gases exchanged diminish, the ventilation increases in proportion and thus the excessive activity of the exchanges is maintained to the very last. As the disease yields to treatment and the patient is recovering, this peculiar relationship becomes less and less pronounced. Their researches have extended over seven years and they have studied the respiratory chemistry of forty other diseases, in none of which are these phenomena found in anything like the same degree. They divide the descendants of consumptives into two groups, *i. e.*, those in whom the respiratory exchanges are normal and those in whom they are exaggerated, the former escape tuberculous infection, but the latter are predisposed to the disease. In arthritism, on the contrary, the exchanges are below the normal, which suggests an explanation for the known antagonism between the conditions.

There has been a great deal of aimless speculation and eminently unscientific writing about the pretuberculous state. It seems to me that all of us who have not tuberculosis may be said to be in the pretuberculous state. I fail, however, to see in what the prodromal stage of phthisis differs from that of any other debilitating illness before the characteristic symptoms have appeared. In order to take advantage of every possible chance that our patient may have, it is of course imperative that we should recognize the disease at the earliest possible moment. We have been prone to assume that the absence of the bacilli from the sputum relieved us from any further responsibility, but that this does not necessarily imply a healthy condition of the respiratory tract is evidenced by the fact that in 408 indubitable cases of early tuberculosis Turban failed to find the bacilli in 59.8 per cent., so that in the early stages we are little better off for a decisive sign than before Koch's discovery.

Another condition adverse to early diagnosis is that we rarely have the opportunity of examining our patient at the very inception of his trouble. The onset is so insidious that people are apt to pay very little attention to the slight feeling of debility they experience, and when at last they think it worth while to consult us the evidences of trouble are widespread and much valuable time has been lost.

The administration of tuberculin in the human subject for diagnostic purposes seems to me to be indefensible from any point of view, although I realize that it is a routine procedure with many capable and conscientious men. In a case in which there is a reasonable doubt, is it not better to temporize, at the same time caring for the patient, than to run the risk which, though remote, is none the less real, of adding a firebrand to the latent spark of disease and destroying all his chances? This has happened on more than one occasion. In fact the tuberculin reaction is not unimpeachable as regards infallibility. it occurs with some regularity in syphilitics. Fuerst[2] reports an instance in a hysterical patient in whom injection of tuberculin was followed by a typical reaction, but, strange to say, the same phenomenon occurred later after an injection of distilled water and again after the insertion of an empty hypodermic needle.

The use of the various serums seems to be entirely unreliable so that at the beginning of the twentieth century our main reliance must still be on the clinical history and the physical signs.

Aspiration of the lung has been recommended in doubtful suspected cases, where there are no bacilli in the sputum. The value of our examination will depend very much on the care with which it is made and a judicial appreciation of the weight of evidence.

In the routine examination of patients in whom there is any suspicion of even a tendency to tuberculosis, it is well to commence with a careful consideration of the personal and family history. If heredity be not an important factor, the occurrence of other cases of tuberculosis among a patient's associates (or family) is suggestive of opportunities of exposure. All the possible morbific influences which may be operative in the given case should be sought out and their effect estimated. It has been conclusively shown that density of population bears a direct relation to the development of tuberculosis only second to close confinement, so that we learn that a large proportion of prisoners die of tuberculous diseases—four times as many as people who are at liberty. Practically all cloistered nuns meet the same fate and the mortality from phthisis is terrific among those who spend their lives in laborious indoor occupations. Penury also exerts a powerful influence by depriving the unfortunate poor, not only of the comforts, but of the bare necessities of life. Some statistics compiled in Hamburg show that tuberculosis is only one-half as common in persons whose income exceeds $500 a year as in those who are compelled to live on less than that amount.

As to the actual symptoms on which we may place reliance in reaching a conclusion, I think they may be enumerated in the following order: An insidious perversion of general nutrition, with

varying degrees of gastric and intestinal disturbance, which notwithstanding all the refinements of the analyses of the digestive secretions and products, does not seem to have any distinctive characteristics. Klebs[3] attributes these disturbances to atrophy of the thyroid gland and suggests thyroid medication as a remedy. Directly consequent on nutritive disturbances are impairment of muscular vigor and resistance to fatigue, with progressive chloranemia and loss of weight.

Several writers have attached considerable importance to persistent pupillary dilatation as suggestive of a possible future development of tuberculosis.

A persistent tachycardia which can be laid to no other cause is, I believe, an indication of commencing trouble in many cases. In my opinion and experience, one of the weightiest and most universally observable symptoms, even in very early stages, is some abnormal variation of the temperature. That in itself, if only of a very slight range, without other discoverable cause, would lead me to decidedly more than suspect a tuberculous focus somewhere. A variation of not over a degree, particularly with a subnormal morning temperature even when there is no afternoon rise, is to my mind exceedingly significant, and when in addition there is even a slight elevation after moderate exercise I should consider the diagnosis as practically made. These peculiarities of temperature may sometimes be made out during menstruation when they are not discoverable during the intervals.

I am inclined to question the possibility of there being afebrile cases of tuberculosis; they are at least anomalous and if frequent records were systematically taken would, I believe, almost invariably show material fluctuations. I have at present under my care a patient far advanced in the third stage, whose temperature has never been above normal when I have had the chance of taking it, but I do not believe that such a thing occurs more than once in a man's experience. When there is a persisting abnormal temperature range and there may be a question between tuberculosis and some form of malaria, external applications of guaiacol will sometimes clear up the doubt by relieving the fever of tuberculosis, or leaving that of malaria uninfluenced.

Inspection of the thorax in the early stages is of little value, for ordinarily the changes in external configuration are to be attributed to rather extensive internal changes. On the other hand, a thorax which is below the proper proportionate size and of bad shape, with an unnaturally small vital capacity, is a strong presumptive indication that its possessor is more than usually liable to tuberculosis. Mensuration in itself is of no special help in early diagnosis.

The first deposits of tubercle are ordinarily about or in the walls of the smaller bronchioles and these deposits may be localized or pretty widely scattered. At first they are generally so unextensive as not to influence the percussion note to any appreciable degree. It has seemed to me that I have experienced often a sensation of resistance to the percussing finger, long before I could appreciate any special change in the quality or pitch of the note elicited. The signs made out by auscultation may be slight, but in many instances, if discoverable at all, they are enormously important. The phenomenon of so-called cog-wheel respiration, if found in successive examinations in the same locality, is more than suggestive and the same may be said of any circumscribed alteration in intensity, pitch or rhythm of the respiratory murmur which is independent of other recognizable cause. Any evidence of a catarrhal condition of the bronchioles which is not obviously transitory is diagnostic and with a little care the signs may be elicited when even on a first careful examination they may seem to be absent.

The ratio of basal to apical involvement at the beginning of a tuberculosis is 1 to 500, and therefore our keenest attention should be directed to the apices, far more often to the right than to the left. Frequently auscultation of the anterior surface will be entirely negative and yet in the supraspinous fossa and along the inner border of the scapula we will find what we are in search of. Very often a sharp cough followed, as it always is, by a quick, deep inspiration, will reveal a few fine moist râles which are inaudible on ordinary deep breathing, and the character of the succeeding expiratory sound will also declare itself. In some cases small doses of iodide, 3 to 5 grains t. i. d., for a few days, have often helped to demonstrate conditions, which have been undiscoverable before. Not seldom during menstruation physical signs will become apparent which are absent or indistinguishable during the intervals. Unnaturally clear transmission of the heart sounds without consolidation is often encountered and is suggestive.

Skiagraphy has lent and will lend to a much greater extent in the future, as we become more expert in its application, strong corroborative testimony in doubtful cases; and I believe it will at all events lessen the number of reported primary laryngeal involvements which some of our clinical experts are fond of presenting. Occasionally laryngoscopy will reveal indubitable trouble when other signs are wanting. The anemia of a tuberculous larynx and the peculiar character of the changes in its tissues are unmistakable to the experienced eye even if they constitute the whole obtainable evidence of disease, but I am persuaded that in these cases, if our senses were sufficiently acute, we would almost invariably discover other foci of infection.

As to the symptoms of cough and hemoptysis, we may consider them of importance only when we can assure ourselves by minute examination of the upper air-passages, that they are not of local origin. To recapitulate, we are justified in assuming tuberculosis on the evidence of otherwise unexplained gastric and nutritive disturbances, with persistent tachycardia and fluctuations of temperature, although slight, especially with an increase after exertion—particularly if

the personal history gives a coloring of probability. We may be absolutely certain of our diagnosis if, in addition, the slight physical signs I have mentioned are discoverable, and notwithstanding a history of cough and possibly hemoptysis, we may presumptively discard the probability of tuberculosis if these phenomena are absent.

Cases of basal origin are usually the result of pleural infection. In fact some observers contend that almost invariably pleurisies with effusion, if not traumatic, are tuberculous in character, whether serous or purulent. Any intrapleural effusion which is tardy in clearing up excites our apprehension and surgical intervention should not be delayed unduly. Here microscopical and bacteriological examination of the fluid is of paramount importance.

The prognosis of pulmonary tuberculosis is perhaps the most uncertain matter in the domain of medicine. The site of the original lesion may exert some influence on the course of the disease. Primary basilar involvement is considered much more serious than apical—a left apex lesion seems more apt to clear up than a right. Variations in the morphology of the bacilli and in their tinctorial reactions are said to be of prognostic value, but such distinctions are scarcely of use to us as clinicians practically, as they imply a degree of expertness in laboratory technic of which few men in active practice are possessed.

Michaelis[4] contributes an interesting article on the diagnostic and prognostic value of the diazo-reaction. Its persistent recurrence indicates tuberculosis and its presence in ascites or meningitis points to the tuberculous character of the lesion. It occurs independent of fever, of the number of bacilli or of the amount of the sputum. It is most common in advanced cases and is an unfavorable prognostic; when present, death can usually be expected within six months. Of 111 cases which gave the reaction, 80 died within that time; of 56 where it was absent 3 died. Early hemoptysis is said to be a favorable prognostic, although when accompanied by a pronounced pyrexial movement it is bad.

To attempt merely an enumeration of the various remedies which have been tried in the treatment of tuberculosis would carry me far beyond the time allotted for this paper. It is a sad commentary on our therapeutic knowledge and attainments that to-day the most sanguine clinician claims but a very little larger proportion of cures of tuberculosis from the sum of our modern achievements than the pathologist told us years ago that he found on the autopsy-table of tuberculous lesions apparently spontaneously healed.

Baldwin[5] reports the results of treatment in Trudeau's sanatorium—where the results have been as gratifying as anywhere in this country—1,200 patients were admitted, 900 advanced and 300 incipient cases; 1,176 were discharged, 300 of them absolutely without symptoms of disease. In other words, 68 per cent. of incipient and 11 per cent. of advanced cases were discharged cured. According to various observers, healed lesions have been observed in from 20 to 50 per cent. of all autopsies.

I think I am justified in saying that no form of treatment, no drug that we have ever used, have specifically affected the course of pulmonary tuberculosis in the slightest degree. Osler says: "Arrest or cure of tuberculosis is entirely a question of nutrition and the object of any treatment is so to improve the patient's general condition that he may be able to withstand the influence of the morbific agent, etc."

Without particularizing, we can state axiomatically that the various attempts at serumtherapy have been up to date absolutely inefficacious, and the same may be said of any and all medicinal preparations of which I have any knowledge—indeed, there are some of the latter which I believe have been productive of much harm. Nevertheless the outlook was never so encouraging for the future, nor the probability so strong that eventually this great curse of the human race will be vanquished. The advocacy and ultimate discarding of the various forms of medication are in the right line of investigation and perhaps ultimately by a process of exclusion, we may have left in our armamentarium some few agents of value, when the chaff shall all have been rejected.

The surest way to cure tuberculosis is to prevent it, and this is largely within the province of those concerned in caring for the public health. That the hope of stamping out tuberculosis is not Utopian, is evidenced by the decrease in the death-rate of cities where modern sanitary methods prevail. Thus, in Berlin the deaths have decreased from 3.42 per thousand in 1883 to 2.30 per thousand in 1894; in London from 2.86 per thousand in 1851-60 to 1.83 per thousand in 1895, and similar statistics might be multiplied *ad infinitum*.

The point is that it has been demonstrably possible to diminish the mortality over one-third in the last twenty years and that, too, in many instances, almost against the will of the public, who, especially in our country, resent any and all interference with their freedom of action, even when it tends to their own destruction. I wish to remark here that I believe future results will come mainly through the efforts of such beneficent organizations as the Pennsylvania Society for Tuberculosis and similar associations, whose work in instructing the lay mind as to the reason and reasonableness of sanitary recommendations has been productive of so much good already.

But to return to the domain of the practitioner, there are some matters of personal hygiene and prophylaxis as applied to his individual patients that he can not ignore without being distinctly culpable. Ward[6] made observations in his own house for a period of three weeks during November. He found the mean relative humidity of the inside air was 30 per cent. with an average temperature of 69° F., while the outside temperature was 36° F. with a mean relative humidity of 71 per cent. This shows our average inside air to be drier than that of most desert climates and indicates the extremes to which, as a result of the

refinements of modern luxury, our organisms are subjected. Can we be expected to preserve our powers of resistance under such conditions? Another factor is the utterly irrational way in which most people dress. The time is ripe to start a crusade, for one thing, against the all-wool-underclothing delusion with its potentialities for harm, and endeavor to inculcate some ideas of proper clothing in the lay mind.

Again I believe it to be a most important thing in any given case, whether predisposed to tuberculosis or not, that the patient should be assured of the protection given by an approximately normal condition of the upper respiratory tract. While catarrhal conditions of the nose and nasopharynx never directly "run into consumption," as the laity express it, they assuredly do increase the liability to it. Particularly is this the fact in regard to the various obstructive lesions which induce the necessity of mouth-breathing and especially the lymphoid hypertrophies so often encountered in children. Aside from the discomforts induced locally by these growths, their effect in producing general nutritive disturbances is enormous, which can easily be demonstrated by removal of hypertrophied tonsils and adenoids, in many cases the improvement in general health being so great that the patient is scarcely recognizable after a few weeks. The same thing applies to other forms of nasal deformity causing obstruction. Aside from their general pernicious influence, a specific danger exists in the inviting portals of entry offered to pathogenic germs, particularly to those of tuberculosis, by the enlarged and diseased masses of lymphoid tissue. I doubt if they are often the seat of primary tuberculous lesions, but the researches of Goodale, Packard and others leave little doubt that they have been responsible for many infections of the general system.

In the management of the developed disease there are a few points of which I would like to speak, naturally first of climate. The consensus of opinion of the foremost phthisiologists of today is that the popular ideas of climatotherapeutics are based on entirely erroneous foundations. In other words, there is no specific virtue in any special health-resort and the theory that altitude has any special influence is at last fortunately practically exploded. The indiscriminate prescription of climatic change without due regard to the exigencies of the individual case has probably done more harm, shortened more lives and destroyed more possible chances of recovery among consumptives than ignorance or faulty application of any other remedy that has ever been employed in the treatment of phthisis. In this connection a word about ozone of which we hear so much in connection with the beneficial effects of health-resorts. It is present in atmospheric air in the proportion of one part to 700,000. "The value of its presence would appear to be more an evidence of atmospheric purity than as a disinfectant, as it is absent where injurious decomposition is going on." Thompson as a result of his experiments on the action of ozone and its compounds reaches the conclusions that "ozone is of no value to the tissues, whether inhaled or drunk in fluid preparations, and it may be exceedingly harmful. Ransome and Foulerton[7] have found that ozone in concentrated form had little or no effect on the vitality or virulence of bacteria.

The results of the possibilities of continuous out-door life in the treatment of tuberculosis have been a revelation to us and by them the absurd claims of enthusiasts and self-interested climatologists have been sufficiently answered. While sanatorium life is perhaps the desideratum for most consumptives, there is no reason why practically the same results cannot be reached in many instances without sending them from home, granted that their surroundings are fairly decent. If carried out systematically and conscientiously, I believe this method is applicable to almost all patients and will give them the greatest proportion of chances, but with the present enthusiasm there is certainy a danger that it may be overdone and to be most effective it must be begun in the early stages. It will only discredit this method to apply it indiscriminately to all patients irrespective of each one's special environment and peculiarities. I certainly believe that it offers to us more promise than any plan which has preceded it. I must take this occasion to add my word of praise and indebtedness to Dr. S. A. Knopf for his masterly articles on this phase of the tuberculosis question.

We are all much less sanguine as to the future of serumtherapy in tuberculosis than we were some years ago. There are practically insurmountable intrinsic difficulties in the way of treating specifically such a disease as tuberculosis, for, after all, that which kills the patient is not ordinarily the tuberculous disease itself, but the concomitant secondary infections. According to Petruschky's observations in Koch's Institute,[8] tuberculin is of no value in cases of phthisis with secondary infections—and we practically never see them without—and Kleb's preparations have had entirely negative results.

Harper[9] writes a suggestive article on the administration of urea to tuberculous patients. He calls attention to the fact that carnivora rarely become tuberculous and that gout, rheumatism and allied diseases seem to be really antagonistic to the development of tuberculosis. He failed to obtain growths of the bacillus in meat-broth containing urea, but in his control tubes where it was absent, the germs grew rapidly. He proposes to treat tuberculous patients with a liberal meat diet and with the exhibition of additional urea. So many observers have dwelt on this antagonism between tuberculosis and the uric-acid conditions that there must be some reason for their ideas, and I think most of us must have seen instances in our own experience which seemed to corroborate the impression.

In the symptomatic treatment of tuberculosis there are a few routine procedures against which I desire to enter a formal protest: First, against

the use of cod-liver oil. This may sound heretical, but I am convinced of its truth. It acts as an alterative by changing decidedly the oxidation processes of the system. But, unfortunately, its alterative effects are in the wrong direction, decreasing the perfection of the proteid oxidation and often depriving the unfortunate patients of the single chance of recovery they might otherwise have retained. The free ingestion of it rapidly decreases the urea in the urine and increases the incomplete or imperfect products of nitrogenous waste. The more perfectly it is emulsified, the more detrimental it becomes, because thus it is more palatable and is less likely to produce digestive disturbance and to be therefore refused entrance to the system. The emulsion also favors the absorption of immoderate quantities, thus exhausting the oxygen supply and rendering the suboxidation of the proteid molecule, with all its ill-effect, doubly certain. It disturbs digestion and prevents the utilization of other and more valuable forms of foodstuffs.[10] Second, against the indiscriminate use of opium derivatives and cough syrups, which upset the patient's digestion and nutrition and thus work him incalculable harm. My personal experience with heroin has been uniformly disappointing. Third, against the treatment of the septic fever by the coal-tar antipyretics.

For the relief of cough, for freeing the lungs from accumulated secretions and for controlling the symptoms of pus absorption, we have in intratracheal medication by means of the laryngeal syringe a means of treatment as far superior to gastric medication in practice as it is in theory and whose technic is entirely within the grasp of any man who desires to acquire it. No cumbersome apparatus is required, it is less unpleasant to the patient than the frequent administration of drugs and it does without fail what ordinary medication often misses—it relieves the symptoms we desire to mitigate. But it is in the treatment of the horrible lesions of laryngeal tuberculosis that the laryngeal syringe finds its widest field of usefulness, and here the applications of orthoform, as used by Freudenthal, are of incalculable benefit to the sufferer and often obviate the necessity for the more radical treatment by surgical means, which notwithstanding enthusiastic advocates, proves often absolutely disappointing if not actually injurious.

To those who have the time and facilities to command its aid there is nothing that will give the results, aside from the open-air treatment, and that can be obtained with the pneumatic cabinet. If these two agents can be employed in conjunction, I believe that almost any case can be benefited if seen sufficiently early. Antiseptic inhalations are of great additional utility and while, of course, none of these things have the least specific effect on the bacillus, they do influence materially and definitely the course of pulmonary phthisis as we see it clinically. After daily employment of these methods for more than thirteen years I am convinced that these claims are capable of demonstration and that therefore the cabinet and antiseptic inhalations constitute to-day the most rational and effectual methods of mechanical and medicinal treatment of tuberculosis at our command and when fortified by what is more important than all else—open air and good food—they are as nearly a specific as anything can be.

THE PREVALENCE AND TREATMENT OF TUBERCULOSIS AMONG THE POOR.[1]

BY H. L. FANCHER, M.D.,
OF ISOLINE, TENN.

Every year since 1882, when Koch announced the discovery of the tubercle bacillus, tuberculosis has excited an increasing interest. For several years after this wonderful discovery medical men looked forward to the time when Koch or some of his contemporaries would discover a specific for this widely disseminated disease. In 1890 Koch's tuberculin was put upon the market and various specific nostrums and fumigations from the laboratories of the quacks were added. From that time to the present, we have seen some of our most energetic pathologists spending the best years of their lives searching for a cure and a preventative, but the tale remains to tell itself.

Still tuberculosis claims one death in seven. The pulmonary form alone claims in the Greater City of New York as its victims between eight and nine thousand annually, seventy-five per cent. of this number came from the tenement-houses, while only about ten per cent. came from the wealthy. From these statistics we may safely say that from eighty to ninety per cent. of the patients dying of tuberculosis in the City of New York came from the bread-earners. Statistics from other cities show a similar death-rate from this one cause. The City Fathers have become alarmed at these figures, and are preparing to care for their consumptive poor.

If correct statistics could be gotten from the rural districts of Tennessee, I am quite sure it would open the eyes of the most drowsy dreamer. The prevalence of tuberculosis on Cumberland Mountain is simply appalling. You can hardly find a person from the rural districts of the Cumberland Plateau whose family history is not darkened by this dread scourge of humanity. This statement would hardly seem credible when we think of the high altitude, the pure dry air, and the "pine forests liberating an extra amount of ozone," but if you were to go with me into the homes of those poor mountaineers, you would at

[1] Read before the Upper Cumberland Medical Society, at Cookville, Tenn.

once see the plausibility of my statement. They are poorly fed and poorly clothed. They usually have large families and small houses; exposed to all the hardships that a poverty-stricken people are subject to, without anything like sanitation in and around their houses. Their drinking-water usually comes from a little surface spring, situated at the head of a hollow just below their house, which furnishes an outlet for the sewerage of all their premises.

In discussing the treatment of tuberculosis, I would like to quote to you and emphasize the words of Dr. S. A. Knopf of New York. In a paper published in the MEDICAL NEWS of March 9th he said: "Consumption is an eminently preventable and curable disease. It is curable in nearly all climes. All that is needed for the treatment of consumption is relatively good and pure air, good food and plenty of it, the best hygienic and sanitary conditions, and a willingness on the part of the patient to submit himself to the constant guidance of his physician. Consumption is not merely a medical, but also a social disease. Society must come to the aid of the physician. He alone cannot cope with this affliction. If society, if our wealthy citizens, if the many noble men and women, willing and able to help, could only know the life-history of some of these consumptive poor, they would realize what I mean by saying, consumption is a social disease, and they would see at once where their duties lie."

Most of the large cities have equipped special hospitals for their consumptive poor, and Texas and Alabama have purchased and equipped separate farms for their tuberculous convicts and claim that under this system the health of such convicts has improved so much that instead of being an expense, they are turning over to the State annually a handsome profit on the investment.

Massachusetts, New York, Pennsylvania and Michigan have, through their legislative bodies, built State sanatoria for the care of their consumptive poor.

Dr. Pryor of Buffalo said at the second annual meeting of the American Congress of Tuberculosis, held in New York, May 15, 1901, that 14,000 patients die in the State of New York every year of tuberculosis, and that seventy-four per cent. of these he believes might be saved if the correct diagnosis were made in the incipient stages and appropriate treatment instituted. The rich can go to private sanatoria, but the poor must die unless the State makes some provisions for them.

The poor throughout the rural districts of Tennessee need to be taught the lessons of hygiene and sanitation, and one of the best ways to do this is to get our State Legislature to help us build and equip one or two sanatoria, where selected cases may be given proper treatment and taught the lessons so needful to this class of people.

As Dr. Knopf said in the address previously mentioned, "A sanatorium similar to the one in the Adirondack Mountains is not only a healing institution, but also a school of hygiene where the patients will learn from actual experience how to take care of their expectorations, how to protect others from infection and themselves from re-infection, what to do and what not to do in order to get well and remain well."

Until we can get these necessary sanatoria, we must take advantage of the best means at hand, and let every case be a law unto itself. Each system has its virtue, and we should adopt the true allopathic method of taking good from all sources. I think in a great many cases of pulmonary tuberculosis, and especially where only one lung is involved, Dr. Murphy's method of injecting nitrogen gas into the pleural cavity is an ideal treatment. It is a clinical fact proven by Drs. Murphy, Wood and others that when the lung is collapsed, hemorrhage stops, night-sweats occur less frequently, and the general conditions of the patient materially improve.

It has been known for some time that if pneumothorax develops in the course of pulmonary tuberculosis, it will greatly improve or cure the tuberculous area. Pleurisy or pneumonia occurring in the course of consumption will invariably benefit the tuberculous condition. Dr. Loomis correctly states that "these marked improvements are brought about by collapse and immobilization of the lung, that the lung is forced to rest, and rest checks the development of infection in new regions and yet does not interfere with the circulation. It enforces drainage of secondary deposits through the bronchi, approximates the walls of cavities and thus gradually empties them, diminishes the lymphatic circulation and favors the encapsulation and cicatrization of tuberculous areas.

As to the hydriatric treatment advanced by Dr. J. H. Kellogg of Battle Creek, Michigan, it is a very beneficial adjunct to any course pursued, and especially in those cases in which the eliminative powers are weakened.

Open air and sunshine are always necessary. A selected course of tonics is needed in most cases, but as no drug has any special control over the development of the disease, the medicament should be carefully chosen for each individual case.

As to the treatment of tuberculosis of the bowels, which is a very common affection on the Mountain, I have but little to offer. The general rules of hygiene which are applicable to the pulmonary form; nutrients, tonics and digesters are about all the means we have with which to combat this trouble. Alimentation is imperfect and nutrition greatly impaired.

Swimming Pool for Insane Ward.—A building 31x62 feet in size is to be erected at the Pennsylvania Hospital for the insane as a swimming pool for the woman's department. The building will cost $18,000 and is one of the many improvements for bettering the condition of the insane for which this hospital has become justly famous.

THE CROWDING OF CONSUMPTIVES INTO THE MUNICIPAL GENERAL HOSPITALS.

BY WILLIAM RIDGELY STONE, M.D.,
OF NEW YORK.

THE Board of Health of this city is making most praiseworthy efforts to check the spread of tuberculosis, but despite their meritorious work they have evidently overlooked one fruitful source of infection.

The municipal hospitals of New York are now crowded with cases of tuberculosis in various stages. Most of these patients are of the uneducated classes, totally oblivious of their condition and unable to understand that they are a menace to their fellow citizens.

In one of the wards of a municipal hospital having the capacity of twenty-eight beds, there are assigned more than forty patients. More than twenty of these patients have been shown to be tuberculous. In the other medical wards of the same institution there are from ten to twenty such patients. In spite of a most efficient corps of nurses and orderlies, it is impossible to make these unfortunate sick understand the necessity of complying with rules laid down for the prevention of the spread of this dread disease. They will not use the sputum-cups provided for them, but most often expectorate upon the floors of the wards, upon the bed-clothes or into the registers set into the floors. These latter places are their favorite cuspidors. The result of this carelessness is most evident. The sputum is quickly dried by the hot air and then blown into the air circulating about the wards, to be inhaled by all the other patients and attendants. To one at all familiar with the manner of the spread of this disease, the condition will seem criminal. The patients in the wards are all in a condition of lowered vitality and are thus ideal hosts for the invasion of the tubercle bacillus. That this is true, the following facts will easily show:

Case I.—A strong, hearty, once robust truckman was admitted to one of the medical wards last winter suffering from rheumatic fever. His chest was perfectly normal; there was not the slightest cough present. The rheumatic fever was quite intractable and the attack lasted about six weeks. After being out of bed for a while, he was about to be discharged from the hospital, when he was taken with a severe chill, headache, nausea and vomiting, and diarrhea. His temperature, pulse and respiration rose above normal, so that he was forced to go to bed. The following day he developed bronchitis and other symptoms which suggested typhoid or some such continued fever. A few days later his sputum was examined and the tubercle bacillus was found present in large numbers. In about six weeks he died. Autopsy revealed the cause of death to be general miliary tuberculosis. No other evidence of lung involvement could be discovered.

Case II.—Patient, male, between thirty and forty years of age. Admitted to medical wards complaining of rheumatism in left ankle. Examination showed the case to be one of probable gonorrheal arthritis. Heart and lungs were normal. For four or five weeks the patient's ankle was treated by hot-air baths, with marked improvement. At this time he seemed to be in excellent general health, when one day he was taken with a severe chill, headache, nausea, and pain in the side. His temperature, pulse and respiration arose above normal. Physical examination showed consolidation of the left apex, and the case was thought to be one of lobar pneumonia. The temperature continued high and the crisis was awaited. At the end of two weeks no fall of temperature taking place, the sputum was repeatedly examined and at last the diagnosis of tuberculosis was confirmed by the presence of the tubercle bacillus. Six months later the case came to autopsy, showing tuberculous cavity formation and other such involvement.

Case III.—Child, nine months old. Mother was admitted to the hospital in the seventh or eighth month of pregnancy, complaining of rheumatism in her left knee. From an examination of the vaginal secretion, the probable diagnosis of gonorrheal arthritis was made. The examination of her thorax was negative. Various treatments were given her without relief of the arthritis. She came to term and was delivered of a large, healthy female child. After the period of her puerperium she was sent back to the medical wards, where she remained for six months. Finally, operation was deemed advisable and she was sent to the surgical wards. All this time her child seemed perfectly well. Shortly before the mother was operated upon, the child became fretful and irritable. It soon lapsed into a semiconscious condition and then developed symptoms of tuberculous meningitis. In about a week's time the child died. Necropsy showed tuberculous meningitis and general miliary tuberculosis.

These three cases are reported to show the alarming conditions of affairs which exist in the very locality where one would least suspect it. The writer has witnessed nine such cases in his own personal experience and has been able to collect as many more. Besides the cases among the patients several female nurses and many male orderlies have during the last two years been forced to leave one of the largest public hospitals in this city, and, in fact, in this country, because of pulmonary tuberculosis contracted while on duty in the medical wards of the same institution. Furthermore, during the same period of time, two of the medical attendants have become infected by the tubercle bacillus.

Many of the tuberculous patients are perfectly able to be out of bed and about the hospital grounds, but, unfortunately, in the majority of instances they cannot be discharged, because they are destitutes. They must be accommodated with beds, and inasmuch as there are other patients less able to sleep away from the overcrowded medical wards, the consumptives are sent

to sleep in the vacant beds of the surgical wards. Here there are cases recently operated upon or recovering from the debilitating effects of operations. These patients are subjected in their low state of vitality to the easy possibility of tuberculous infection, and such infection has taken place.

There can be no question as to the seriousness of placing tuberculous patients in general medical wards under such conditions. The city or community owes it to individuals that they be better taken care of. Many a poor patient suffering from disease can become a useful citizen. And even though the municipal Board of Charities hold poverty to be a crime, the punishment that they are meting out to these unfortunates is entirely too severe. It would seem that the ancient barbaric idea of the lethal chamber were once more to come into vogue. Should one deliberately place into the food of another the germs of typhoid, Asiatic cholera or what not, would he not be punished as a malefactor? Yet the municipal authorities place patients in hospital wards the air of which is pregnant with the germs of tuberculosis.

TUBERCULOUS OTITIS MEDIA, MASTOIDITIS AND MENINGITIS IN AN OTHERWISE APPARENTLY HEALTHY ADULT. BRIEF REPORT OF A CASE.[1]

BY JAMES FRANCIS MCCAW, M.D.,

OF WATERTOWN, N. Y.;

OCULIST, AURIST AND LARYNGOLOGIST TO THE CITY HOSPITAL AND TO THE JEFFERSON COUNTY ORPHAN ASYLUM; FELLOW OF THE AMERICAN LARYNGOLOGICAL, RHINOLOGICAL AND OTOLOGICAL SOCIETY, ETC.

TUBERCULOSIS, on account of the widespread interest which has been manifested for several years by the medical profession in the endeavor to check its ravages, the high mortality and the great importance of an early recognition, especially in those cases affecting the middle ear and its adnexa, make it of interest to us, not only as physicians, but as otologists. The case I have to report to this Society is of unusual interest, clearly exemplifying the error in diagnosis and treatment which is apt to be made in cases where mixed tuberculous and pyogenic infection is present.

In this case was it made especially difficult, from the fact that the patient was in deep stupor when seen, and my advice had to be given, based entirely upon the history and physical examination. On account of the findings and the apparent demand for immediate surgical interference, I doubt if I should have examined the secretions for bacilli had means been available, for nothing was found in the history or in my examination at that time which suggested to me the probability of a tuberculous process.

The following notes of the case, with the findings at the autopsy, wil[1], I trust, be of interest:

W. H. W., male, adult, forty-five years of age, was seen by me in consultation on December 11, 1900, when the following history was obtained. His mother and father have always been healthy; are still living at an advanced age. There are two brothers and one sister, who are living and healthy. The patient suffered from measles when a child. At the age of twenty-five years had typhoid fever; since then has enjoyed perfect health, attending to his business, that of a mechanic, regularly. About one year ago, without apparent cause and only the slightest suspicion of pain, a thin discharge made its appearance in the left ear which was given little thought and allowed to take care of itself. From time to time after this, at intervals of one or two months, he suffered attacks of pain in and around the ear, followed by an increased amount of discharge and relief from his symptoms. During these exacerbations there was sensitiveness to pressure and occasionally slight swelling about the ear, especially behind it. His family physician told me that up to the beginning of his last illness he had noticed little change in his physical condition. His present trouble began seven weeks prior to my seeing him, with what was supposed to be an attack of influenza; sore throat, nasal discharge, headache and temperature about 100° F. He was confined to his home for several days, after which he resumed work and was able to continue nearly two weeks, but during this time was not well, suffering from anorexia, occasional vomiting, persistent headache and general malaise. About this time he had one of his attacks of pain and sensitiveness around the left ear, which compelled him to remain in bed and the usual hot poultice was applied. In twenty-four hours there was an increased discharge of pus with complete relief of pain. Following this he gradually grew worse with exacerbations of pain and intervals of relief, loss of appetite, constant headache, an irregular temperature, gradual exhaustion, and for the last week, remained in a drowsy condition, but from which he could be aroused and would answer questions; this changing to a deep stupor twelve hours before I saw him.

Examination.—Patient was emaciated, face of an ashy gray color, pupils equally contracted and no paralysis detected. He could not be aroused from his stupor, but responded to a stimulus. Pulse 58, temperature 102° F., respiration 36. A slight swelling was observed behind the left ear over the mastoid. Pressure over this area elicited pain; shown by the patient's attempt to remove my hand. There was a small amount of foul-smelling pus in the external auditory canal, the membrana tympani almost completely destroyed and only the head of the malleus remained. The tympanic cavity was filled with granulation tissue and pus, with perceptible bulging of the postero-superior canal wall. No glandular enlargements were observed.

It seemed clearly evident that this patient was suffering from an intracranial involvement following a chronic otorrhea, and it was thought that cerebral abscess was the most probable diagnosis. He was sent to the hospital, prepared, and the following operation done the same afternoon.

[1] Read at the seventh annual meeting of the American Laryngological, Rhinological and Otological Society.

The middle ear was curetted and granulation tissue removed, flushed out and the canal packed with iodoform gauze. The mastoid was opened and found completely excavated, the space being filled with granulation tissue and broken down caseating material. There was very little pus found and this was in the region of the antrum. The destruction of bone was widespread; the caries extending upward and forward into the root of the zygomatic process, forward to the middle ear; posteriorly into and between the tables of the occipital bone and inwardly destroying the wall of the sigmoid sinus and the inner table of the skull. All granulation tissue and carious bone was removed. This exposed the wall of the sigmoid sinus and meninges over an area about 1 inch by ¾ inch. These were very much thickened and everywhere studded with small typical miliary tubercles. There were several caseating patches on the wall of the sinus which was, however, still pervious. At this juncture the hopelessness of the case being recognized, the wound was cleansed, packed with iodoform gauze and a large antiseptic dressing applied. The patient died twelve hours later. At the postmortem examination the lungs, liver, spleen and kidneys were found free of tuberculous infection and the mesenteric glands not enlarged. Examination of the head was not allowed. Microscopical examination of scrapings from the middle ear and mastoid demonstrated the presence in abundance of tubercle bacilli and streptococci.

A very pertinent point, and one of the greatest importance in these cases, is that of etiology, for upon our correct estimate of the causal factor depends the ultimate result of treatment. In cases of mixed tuberculous and pyogenic infection in an otherwise apparently healthy adult, we are, I think, apt to be misled in the masking of the tuberculous by the suppurative process. Especially is this true if the patient is seen late in the disease.

The question which suggests itself to me in connection with this case as of greatest interest is, Was this a case of secondary tuberculous otitis media in which the primary focus was overlooked, or was it primary tuberculosis of the middle ear and mastoid with subsequent pyogenic infection?

In the light of recent investigation, tuberculous disease of the middle ear as a secondary involvement is not an infrequent occurrence. This view seems to have been accepted by most observers. On the other hand, the frequency of primary tuberculosis in this region is still in doubt. Milligan in a paper read before the Sixth International Otological Congress states: "In my experience primary tuberculous lesions of the middle ear and adjoining mastoid cells are comparatively common, especially among the children of the poorer classes." In a paper before the New York Medical Association in 1898, Oppenheimer takes the opposite view and says, "The primary form is rarely observed, and then, from the extreme difficulty of eliminating the presence of tuberculous deposits in other portions of the economy, it becomes a matter of hesitancy to decide as to the diagnosis being essentially accurate." While we hesitate to accept either of these views as representing the weight of opinion, the evidence which we have been able to gain in reviewing the literature at our command, together with our clinical experience, does not bear out the views of Milligan, that primary tuberculosis of the middle ear is of comparatively common occurrence.

The observation and clinical experience of most observers go to show that it is comparatively infrequent, but does occur. Recognizing the difficulties in arriving at a correct diagnosis in this class of cases, it would seem that in the light of the clinical history, the findings at the time of operation, the microscopical findings and the subsequent postmortem examination, we had here to deal with a case of primary tuberculosis of the middle ear and mastoid. My only excuse for operating was an error in diagnosis, for the case was beyond help.

In conclusion, I will add that could we get these cases early, before too much destruction of tissue has taken place, they would seem to offer some hope of improvement from radical surgical interference, with subsequent supporting treatment and proper climatic environment.

THE TUBERCULIN TEST: CASES IN WHICH IT SEEMED JUSTIFIED AND DECISIVE.*

BY W. E. CASSELBERRY, M.D.,

OF CHICAGO;

PROFESSOR OF LARYNGOLOGY AND RHINOLOGY, NORTHWESTERN UNIVERSITY MEDICAL SCHOOL; LARYNGOLOGIST TO ST. LUKE'S AND WESLEY HOSPITALS, ETC.

IN an experience the trend of which is largely toward the upper as well as the lower respiratory tract, it should be one's constant effort to establish the real diagnosis in the earliest demonstrable stage of pulmonary tuberculosis. This infection, when present in a latent form, during a slow and insiduous onset and during periods of partial arrest, by impairing the general vitality predisposes to other and more conspicuous complants, prominent among which are catarrhal conditions of the upper respiratory tract. With an irritable throat, a hacking cough, a tendency to hoarseness and an inclination to rhinitis the patient of this class is often ready to believe and sometimes even to insist that he has only "throat trouble" or "catarrh." To demonstrate in such a case an unmistakable underlying tuberculosis in the earliest, perchance, remediable stage, is to render immeasurable service. Others, again, who may be suffering from affections actually limited to the throat or from non-tuberculous bronchopulmonary conditions, are not infrequently in constant dread of tuberculosis and demand of their consultant a positive and speedy opinion which shall either confirm their fears or ease their troubled minds. To announce tuberculosis even ten-

*Read before the American Climatological Association, June, 1901.

tatively to such a patient when in reality it does not exist is perhaps to work a great and irreparable injury.

One meets with no inconsiderable number of patients in whom it seems of paramount importance to exclude positively tuberculosis. It is conceded that to this end, in the majority of cases, a consideration of the symptoms and of the physical condition is entirely adequate, yet in an appreciable minority this evidence because of its scantiness and of possible variations in its interpretation is not conclusive, and conversely the typical, steadily-progressive case of pulmonary tuberculosis may be gauged by a tyro, while the atypical case by reason of minuteness of foci of infection, diminished virulence, increased resistance, favorable environment, latency, fibroid inclusion, arrest, or confusion with other pathogenic infections, may leave an uncertainty in the mind of the expert.

There is a prebacillary stage in the sense that the sputum examination may be negative without disproving the existence of tuberculous infiltration. Confusion arises between the normal relative dulness and harsher respiratory murmur of the right infraclavicular region and the slightest signs of initial tuberculosis at that apex. The temperature when other symptoms are obscure is not always decisive and would best be observed over a period of weeks, even months, if one would attach to it a positively diagnostic import. Subacute inflammatory attacks in the upper respiratory tract, influenza and its after-effects, empyema of the nasal accessory sinuses, prolonged convalescence from acute pleuritis or pneumonia, and the primary and secondary stages of syphilis are the conditions which I have in mind as simulating for a time the unpronounced tuberculous febrile reaction. This is especially true when these affections occur in individuals of relatively light weight, deficient nutrition, sedentary life, poor thoracic development and adverse hereditary tendencies. And then there are prefebrile, interfebrile and postfebrile periods in which the tuberculosis, supposedly for the moment in a state of inactivity, fails to register above 99° or 99.5° F., which does not exceed an occasional maximum normal. There are persons in varied states of simply impaired health or in the midst of an exhaustion incidental to a strenuous life whose afternoon temperatures reach that point.

So also with the rapidity of the pulse. When there is progressive activity of the infective process the resulting toxemia quickens the heart, but in intermediate periods and in latent tuberculosis the pulse-rate may not rise above 80. Stress has been laid upon the inalterability of the rapid pulse-rate by position and the characteristic sphygmographic tracings,[16] but one would expect these also to vary in accordance with the degree of activity, as does the rate itself. Attention is also called to the fact that the arterial pressure in tuberculosis is low, as it is in other forms of anemia, but that blood examinations, with special reference to the low specific gravity of chlorosis, while not an unerring guide, may aid in differentiating the anemias.

Therefore, while it is not contended that the fallacies herewith enumerated are of very frequent interposition and while it is admitted, even urged, that the conclusiveness of the customary methods of examination can be broadened by superior skilfulness and a keen appreciation of certain of the finer phases, such as skodaic tympanitic apical resonance, a heightened pitch of the prolonged expiratory murmur, the relation of height to thoracic perimeter,[1] Roentgen-ray photography, etc.; nevertheless it happens from time to time that cases present themselves in which it is impossible to assert the presence or absence of pulmonary tuberculosis despite a conscientious resort to all of these means, and in them it would seem that the careful injection of tuberculin as a test is both justifiable and decisive. I say justifiable because notwithstanding the commendations of all who have recorded a practical use of the test, including B. Fränkel,[2] Trudeau,[3] Beck,[4] A. C. Klebs,[5] Otis,[6] G. W. Webster,[7] Whittaker,[8] Anders,[9] and numerous others, there is still an aversion to the deliberate injection of the organic toxins of a pathogenic organism, such as the tubercle bacillus, an aversion which by laymen is based upon the mere uncanniness of the idea and by physicians upon the double apprehension that tuberculin may carry virulent tubercle bacilli and that its injection may generalize or re-excite a previously circumscribed, quiescent tuberculous deposit.

These apprehensions have been definitely answered anew by B. Fränkel,[17] who affirms that the tuberculin of Koch is heated in a water-bath to a consistency of one-fifth its volume and then filtered, that therefore it can contain no living thing. The fear of generalization and re-excitation he ascribes solely to the observation that during the early use of tuberculin as a cure dissolution was apparently hastened in certain advanced fever stricken cases, but now, by reason of the many thousand of test doses which have been given without detriment, he holds it proven that the careful application of the tuberculin test can result in no harm.

In the midst of an undue conservatism the decisive value of this test was first forcibly impressed upon the writer by the following case:

Case I.—Mrs. J. A., age 35 years at first examination in 1890; weight 90 lbs.; height 5 ft. 4 in.; anemic, persistent cough, expectoration negative regarding tubercle bacilli; afternoon temperature 99° F.; never above 99.6° unless having acute rhinobronchitis; pulse 90 to 110, weak and compressible; pronounced hypertrophic rhinitis, follicular pharyngitis and laryngeal irritation; chest emaciated, slightly pigeon-breasted, narrow at the apices, periphery 26½ in. Respiratory murmur at left apex approaches bronchovesicular, percussion resonance impaired, but these signs then so slight as to be noted with a question mark. They had become more pronounced in 1892 when also the murmur over the right infraclavicular

and mammary regions lacked breeziness and strength. Certain features were absent, but a provisional diagnosis of partly latent tuberculosis seemed reasonable. The following winters were passed at Colorado Springs, Col.; Asheville, N. C., and Las Crucis, New Mexico, where skilled physicians concurred in the diagnosis. The physical signs did not progress and later the disease was supposed to be "arrested." About 1895 certain neurotic symptoms appeared, hysterical aphonia, high-pitched voice, twitching of the facial muscles, leucoderma and edematous ethmoiditis. A few nasal polyps were removed in 1896 with the comment that these were unusual in tuberculosis. Soon, during an attack of acute rhinobronchitis with digestive derangement, irregular asthmatic symptoms developed which further clouded the original diagnosis. About this time, during my temporary absence, Dr. Boomer injected tuberculin and later I repeated the test, both times without reaction. The final diagnosis is bronchial asthma and pulmonary fibrosis, both of mild degree. At present all symptoms are in abeyance except cough and malnutrition. Weight reduced to 81 lbs.

Case II.—Rev. H. R. O., aged thirty years, well nourished, thick-set and of good color; loss of energy, persistent morning cough and mucopurulent expectoration for nine months; afternoon temperature 98.4° to 99.2° F.; pulse, 80. Three negative sputum tests by Winnepeg Government laboratory and several indecisive physical examinations. Resonance and vesicular murmur at right apex impaired, but scarcely more than the relative difference. Also dulness over a limited area at the left base. No râles. Skiagraph inconclusive. Wants a positive opinion on which to base action regarding choice of climate and pastorate. Tuberculin, .003, caused little reaction, but .006 at 4 p. m. sent the temperature to 101° F. by 11 p. m., together with malaise and chilliness.

The next two cases are of special interest aside from the negative tuberculin tests.

Case III.—Mr. F., aged thirty-two years, weight 137; height 5 ft. 11 in.; temperature 98.4° F.; pulse 65. Always anemic. Felt well till two weeks ago. Then confined to bed two days with cough and pain in right side; at business since, but conscions that right lung fails to inflate. Inspection shows right diminished and left exaggerated expansion, but no interspace retraction, bulging nor adhesive collapse of side. Respiratory murmur over whole right lung deficient, distinctly tubular, but with a light vesicular character when forced, as if adequate air failed ordinarily to enter the lung. Vocal fremitus intensified toward the base. Resonance impaired but nowhere flat or decidedly dull. No râles or creaking. Aspiration negative. No tumor or cause of occlusion of main bronchus. Probable diagnosis, restriction of expansion from thickened and adherent pleura following pleuritis. He applied chiefly for an opinion concerning tuberculosis and willingly submitted to the tuberculin test, which was negative.

Case IV.—J. E. T., aged forty-one years; height 5 ft. 9 in.; weight 128; former weight 150. Temperature 99.6° F.; pulse 96. Had syphilis twenty years ago, Cough and right pleuritic pains for two years. Murmur over right lower lobe elicited only by forced inspiration, weak, distant, not bronchial and with subcrepitation like the creaking of thickened pleura. Resonance impaired but not flat, no fluid, fremitus increased. Sputum negative. Repeated tuberculin tests negative. Rapid amelioration of cough, pain and dyspnea under potassium iodide. One year later, weight 144, pulse 80.

Other instances in which the test proved of value include positive reactions in two cases of early laryngeal tuberculosis (Cases V. & VI.) in which the pulmonary involvement was so slight as to be doubtful. In one the disease progressed but slowly, the test induced submission to suitable treatment, and the patient still survives, well nourished, of good color, fair strength, pulse and temperature normal, larynx cicatrized, but with cough, hoarseness and an infiltration of the larynx. A few tubercle bacilli have since been found in the sputum.

Case VII.—H. E. O., aged twenty-three years, but youthful in development, height 5 ft. 11 in.; weight 125 lbs.; pulse 99, temperature 100° F. Two sisters affected by tuberculosis. He applied for an opinion while suffering from an acute laryngobronchitis. Chest flat and small, shoulders sloping. Murmur at apices deficient, puerile and jerky. After a few days his temperature and pulse had regained the normal. Sputum examination and tuberculin test both negative. He remains well now, two years after.

Case VIII.—Mrs. W., a physician's wife, in whom hypertrophic rhinitis and laryngotracheitis had long been permitted to mask an apical tuberculosis. Temperature 99.4° F.; pulse 79. The positive reaction of the tuberculin test proved sufficiently convincing to induce a correct mode of treatment. Tubercle bacilli subsequently found.

Case IX.—Dr. W., a young woman hospital interne, who by study and confinement had lost flesh, strength and color and in whom incipient tuberculosis was suspected by her colleagues, because of cough and deficient respiratory murmur, was given assurance by a negative tuberculin test by which relinquishment of position was avoided. Recovery ensued through better care.

I have used the test satisfactorily in still other cases, but those described represent conditions in which it proved an essential aid to prompt and precise diagnosis, therefore seeming especially justified. Other circumstances under which it was proposed as suitable, but was rejected by the patients, mostly through interference by other physicians, include a case of hemorrhage, possibly pulmonary but lacking in positive physical signs, one of early circumscribed dry pleuritis in the person of a young physician whose life might have been saved by a timely demonstration of tuberculosis, another of circumscribed dry pleu-

ritis of one month's duration, with pain and friction sounds, all of which disappeared in a week under counter-irritation and sodium salicylate, leaving the fundamental cause in doubt, and one of tuberculous family history, with rapid pulse and normal temperature, with ratio of chest perimeter to height and corpulence reduced, but without other rational or physical signs except slight cog-wheel respiration and perhaps a trifle more than relative dulness at the right apex.

The test quantity of tuberculin is usually stated at .005, although the first dose should be less in order to provide against a supersensitiveness or extreme debility of the patient. In this precaution lies the element of safety. The fact that hypodermic syringes are not usually graduated in the metric system has deterred some from using the test. My method has been to prepare afresh at each injection a 2½-per-cent. aqueous solution of Koch's old tuberculin of which 1 minim, representing approximately .0015, may be the initial dose for a debilitated person or 2 minims representing .003 for one of good size and strength. Failing to obtain a positive reaction, the test is repeated after three days, being trebled in the first instance, that is, 3 minims injected representing .0045, or doubled in the second instance, that is, 4 minims injected representing .006. Thus a conclusion is reached by two injections. The reaction consists of a rise of temperature of about two degrees in from five to twenty-four hours, supplemented usually by malaise, slight chilliness and increased cough, which all subside within twenty-four to thirty-six hours.

Is the tuberculin test always decisive? If one were compelled to answer by an unqualified "yes" or "no," it must be admitted that there are variable factors, such as special susceptibility, exceptional resistance, habituation to toxins, and even a close similarity of other pathologic processes to tuberculosis, which are capable of precluding absolute accuracy or results. Since Koch's description of a typical reaction in himself by an injection of .25 it is known to be merely a matter of sufficiently large dose to cause any person, either normal, indifferently ill or tuberculous, to exhibit a characteristic general reaction. In the non-tuberculous as a rule the dose must considerably exceed .01, while the special affinity of tuberculin for tuberculous tissue causes a reaction to be elicited by a dose under .01, usually .005 or less. It is conceivable that in exceptional instances a natural supersensitiveness toward tuberculin might be found just as certain persons are extraordinarily impressionable to cocaine, turpentine, quinine, etc.; but, while such a heightened susceptibility might underlie a very small percentage of errors it cannot be made to account for eight[10] or nine[11] per cent. of reactions, said to have been produced in healthy persons. The most reasonable explanation of this large discrepancy lies in the recollection that autopsies disclose previously unsuspected foci of tuberculosis in even a larger proportion and that the bulk of the eight or nine per cent., therefore, were probably tuberculous. Practically heightened susceptibility is less apt to vitiate the results, for the reason that the test with reference to pulmonary and laryngeal conditions is needed only when it is a question of incipient, latent or unpronounced tuberculosis in which the patient, not being habituated to large quantities of the toxin already generated in the body, reacts to quite small test doses. For the same reason it is readily appreciated that in advanced tuberculous toxemia reactions are excited only by large doses, with correspondingly lessened safety and dubious results. In such cases the test is not commended and should be but rarely required.

The course of events in the limited series of cases herewith described tends to support the decisive character of the test, but a demonstration from any human statistics is obviously impossible. Verification by autopsy is the only universal proof, hence the value of bovine records. The Illinois State Board of Live Stock Commissioners[12] in a synopsis for the year 1899 shows the smallest percentage of errors yet attained. Of 3,655 cattle officially tested, 560 were condemned, of which all but 8 were found tuberculous at a careful but ordinary macroscopic autopsy, and of these 3 had given only partial reactions, thus reducing the actual failures to 5 or less than one per cent. Eight other cows which had failed to react to tuberculin were also killed on account of actinomysis, mammitis, etc., and found free from tuberculosis. The latter is a small number, but as far as it goes it tends to substantiate the negative value of the test. But it is argued man suffers from other diseases, not present in cattle, which are said to react to tuberculin, notably syphilis and lepra. Additional evidence that this allegation concerning syphilis is correct has just been presented by E. A. Otis.[14] It may cause no local reaction in visible syphilitic lesions. Fränkel[15] refers to a case which concerned the diagnosis between syphilis and lupus of the nose in which tuberculin caused a general but not a local reaction. The local lesions subsequently healed under potassium iodide and the syphilis proved to be complicated by pulmonary tuberculosis which explained the systemic reaction. Tuberculosis exists not rarely in conjunction with syphilis, yet the proportion of reactions in syphilis seems too large for this explanation to be complete. One must, therefore, otherwise exclude syphilis in case of positive reaction. An imperfect reaction is said to occur in certain cases of sarcoma and carcinoma, but the same liability to the co-existence of tuberculosis should be remembered. Lepra is closely related to tuberculosis and a reaction in it, which is said to occur, would seem not unreasonable.

MEDICAL PROGRESS.

Epistaxis.—In severe cases of hemorrhage from the nasal mucous membrane too little attention is paid usually to the fact that the blood is in nearly all cases coming from a very small area and, if this can be located, direct application of pressure or a hemostatic agent will be amply sufficient to control it. T. K. HAMILTON (*Inter. Med. Jour.*, Aug. 20, 1901) deprecates the general use of posterior and anterior plugging of the nares on account of its difficulty, its annoyance to the patient and the danger of sepsis from the putrifying blood-clots. "Bleeding, uncomplicated by rhinal disease, is almost always from the artery of the septum, near its anterior portion." Direct examination with a good light usually discloses the offending point. A piece of gauze or cotton soaked in antipyrine or adrenalin and directly applied is frequently sufficient. If plugging is necessary a long single piece of gauze, dry or soaked in the above solutions and applied from the anterior nares, is better than posterior and anterior plugging, but, if the latter in extreme cases becomes necessary, the cord should be passed through the nares by means of a catheter rather than any instrument. To arrest arterial hemorrhage the galvanocautery is by far the best treatment.

Bacteriology of Gangrenous and Fetid Suppurative Processes.—During the past few years much attention has been directed to the study of anaerobic species as the causative agents in gangrenous and fetid suppurative conditions. So essential have anaerobic methods become that little value is to be placed upon bacteriological investigation into these conditions which does not include anaerobic with aerobic study. In studying appendicitis, postpartum suppurative conditions, genito-urinary infection, purulent otitis, pulmonary gangrene and putrid pleuritis, EDWARD RIST (*Ctlblt. f. Bak.*, Sept. 10, 1901) has availed himself of anaerobic methods and never in any one of these conditions has he examined fetid pus without finding a number of anaerobes present. Artificially cultivated these cause gas formation and putrefaction. He believes that the causative agents of gangrene are anaerobes, since these cause the necrosis of living tissue and produce toxins giving rise to systemic symptoms. As much of the work which has been done in infective conditions has been carried on only under aerobic methods, he believes that the prevailing theories with regard to many of these are open to grave doubt.

Chronic Intestinal Obstruction.—The symptoms present are constipation, eructations, tympanites from gas above the obstruction, diarrhea alternating with constipation, colicky pains, writes D. S. HANSON (*Pediatrics*, Oct. 1, 1901); as obstruction becomes nearly or quite complete, vomiting supervenes. It is surprising how well a child will do when the intestine is reduced to a sixth or an eighth of its normal diameter. In cases of long standing with marked obstruction, the fluid portion of the intestinal contents may be absorbed, causing headache, nervousness, moroseness, foul breath, coated tongue, dry skin, etc. Stomach dilatation is rare, but the colon may become immensely dilated when the obstruction is low.

Oxygen Inhalation.—Many writers have argued from the physiological standpoint that the attempt to use oxygen inhalations for therapeutic purposes is necessarily fruitless. A theoretical discussion of the question by E. ARON (*Berl. klin. Woch.*, Sept. 16, 1901) is followed by a citation of clinical experiments. In cases of chlorosis the result of oxygen inhalation was absolutely negative. In marked dyspnea from cardiac and pulmonary diseases somewhat better results were obtained. Several patients were relieved while oxygen continued to be administered, but no longer; others, markedly cyanotic, denied all subjective relief, and objectively no improvement was seen. So far as subjective findings are concerned, the substitution of ordinary air for oxygen without the patient's knowledge showed that in many instances these are largely due to suggestion. In carbon-dioxid poisoning, inhalations of oxygen are indicated owing to the strong chemical combination found between CO^2 and hemoglobin, which combination is very slowly if at all affected by ordinary atmospheric air, while it is rapidly destroyed by an atmosphere containing a high percentage of oxygen.

Reabsorption by the Pleura.—Although it is well known that the pleura possesses considerable reabsorbing power, the limitations within which such power exists have not been definitely comprehended. The subject has been submitted to experimental investigation by JUL. A. GROBER (*Beiträge Path. Anat. und all. Path.*, Bd. 3, Hft. 2). He considers the anatomical relations of the normal and diseased pleura together with the amount and rapidity of reabsorption by the same. The pleural cavity is in direct communication with the lymph-vessels. The healthy pleura is able to reabsorb foreign bodies and fluids and in every animal an amount proportional to its size in a given time. This is accomplished by diffusion and osmosis, by breathing movements, namely, the pump system of the intercostal lymphatics and the pressure of the lungs against the thorax wall, and the movement of the pleuræ against each other. The reabsorbing power of the inflamed is considerably less than that of the normal pleura. The sound pleura is able to dispose of certain quantities of micro-organisms and toxins without injury to itself. The inflamed pleura does not possess this property.

Pupil in General Disease.—In testing for the light reflex it is a common error that the patient is looking at the source of the light or at some near object. A blind eye will not react to light thrown on its own retina, nor will the second eye, but both will react perfectly if light be thrown on the sound eye. Paralytic mydriasis is seen in progressive paralysis, where at first there was myosis, and in various diseases of the base of the brain affecting the third nucleus or nerve. Irritation mydriasis occurs in cervical spinal meningitis, in the spinal irritation of anemia or chlorosis, as a premonitory sign of tabes, in psychical excitement, and in general paralysis (often in one eye with myosis in the other). While some authorities declare that unequal pupils are always pathological, E. E. JACK (*Boston Med. & Surg. Jour.*, Sept. 26, 1901) has seen inequality last for years from childhood up without other symptoms developing. Irritation myosis occurs in early stages of inflammatory affections of the brain and meninges; later there is dilatation. Paralytic myosis occurs in spinal lesions above the dorsal vertebræ. The best authorities believe that the Argyll-Robertson pupil, reacting in accommodation but not to light, is always a symptom of existing or approaching serious nervous disease. Wernicke's symptom, the hemianopic pupil, is of important localizing value when it can be demonstrated. Hippus, or pupillary oscillation followed usually by dilatation when light is thrown into the eye, is an early sign of a coming paralysis, but is also reported in hysteria and disseminated sclerosis. In the algid stage of cholera the retention of the light reflex implies a good prognosis, its absence the reverse. In diagnosing the nature of intracranial lesions pupillary symptoms, if alone, are of slight significance, except that the lesion must affect the nucleus itself or must be peripheral. If, however, with this isolated symptom there are evidences of involvement of other nerves, the pupilary symptom may become important.

Ringworm and Favus.—Ringworm of the face and body is almost exclusively due to the *megalosporum*, writes A. D. MEWBORN (*Pediatrics*, Oct. 1, 1901), which exists only within the hair, never forms a sheath, and has spores arranged in longitudinal chains. When on the scalp, the favus fungus, *microsporum audonini*, is never found with megalosporum. The microsporum is an endo-ectothrix; the long, slender, jointed mycelium growing lengthwise within the hair, while the closely packed spores form a sheath around the hair, sometimes extending as much as 1 or 2 cm. above the surface of the scalp. Under a low-power lens one of these hairs looks like a glass rod which has been dipped in glue and then rolled in fine sand. The treatment for ringworm used by Sabouraud is to epilate once a week all the diseased hairs, as well as the healthy ones, for 1 or 2 cm. around each patch. The rest of the scalp is shaved, rubbed with a mixture of tincture of iodine, potassium iodide and glycerin, and a cap tied on for protection. The diseased follicles are each touched with croton oil on the end of a toothpick mop. Three or four months is the average time required for cure. Cases of alopecia areata are treated by the Finsen electric light three times a week. The favus cases are treated by monthly epilation and the daily use of a tincture of iodine mixture. Their cure requires four to five months.

Hemoglobinuric Fever.—This fever, seen principally in the South, where it is also known as hemorrhagic malarial fever, swamp fever, or black-water fever, is the pernicious malarial fever in which the urine is loaded with the coloring matter of the blood and has the malarial parasite as an active causative agent. In regard to treatment the profession is divided as to whether large doses of quinine used in such cases may not be the cause of the hemoglobinuria. W. SHROPSHIRE (*Georgia Jour. of Med. and Surg.*, Sept., 1901) reports two cases in which the quinine treatment was thoroughly tried. In one instance quinine in moderate doses had been used in a severe case of malaria and blood began to be passed in the urine. She was then given twenty grains hypodermically every five hours. Cinchonism was caused in a few days, but the bloody urine had ceased and the patient was cured. Another similar case is offered to show that during the administration of moderate doses of quinine, hemoglobinuria may develop, but if the dosage is increased the symptom will clear up, showing that this drug cannot be held responsible for the complication.

Correct Posture.—The proper attitude is not to throw the shoulders back, the chest out, the head up and the chin in, writes J. M. TAYLOR (*Pediatrics*, Oct. 1, 1901), for this means restraint of free movement. A simple rule is to let the shoulders alone, but keep the back straight, hold the chest up and keep the abdomen held in. The pelvis also should be level, not tilted forward, as is commonly the case.

Oleic Acid in Hepatic Colic.—Seventeen cases of hepatic colic are reported to have been successfully treated by means of oleic acid by S. A. DE VEVET (*Rev. de ther. medico-chir.*, Sept. 15, 1901). The action of olive oil in such cases is probably due to its oleic acid. Oleic acid may be used successfully, acording to this author, not only to relieve attacks of hepatic colic, but to prevent them; by its chemical action it prevents the formation of new calculi. From one-half to one gram should be given daily, in capsule, for ten or fifteen days before the approach of the ordinary epoch of attack, if attacks are periodical. After several such courses of treatment the drug may be withdrawn. The alimentary and hygienic regimen ordinarily practised in these cases must not be neglected.

Cerebral Pressure following Trauma.—In examining the contents of the cranium during operation after traumatic cerebral lesions, the dura is found tense and the brain non-pulsating at the cranial opening. This intracranial pressure is not due to the introduction of extraneous substances,

such as blood or clot, as it occurs in the absence of hemorrhages. The determination of the cause of this abnormal pressure is of great interest on account of its practical importance to the neurologist and surgeon. W. B. Cannon (*Amer. Jour. Phys.*, Oct. 1, 1901), after a study of the pathological conditions in traumatic intracranial lesions, the clinical findings in such cases and an experimental inquiry into the cause of brain pressure, arrives at the following conclusions: At the moment of injury the intracranial pressure rises to a height sufficient to check the blood-flow into the brain. Immediately after injury the general blood-pressure usually rises for a moment and then falls. Thereafter a gradual recovery of the normal blood-pressure occurs with an increase in the extent of brain pulsation. The paralysis of the respiratory center following head injury may be recovered from if artificial respiration is persisted in and the heart action remains strong. The primary loss of consciousness after a blow on the head is apparently due solely to circulatory disturbances, although minute changes in the nerve-cells must also be considered. The normal cerebral pressure is about 13 cm. of water. After injury to the brain this may rise to 25 cm. Since this increase is not sufficient to account for the clinical symptoms present there must be secondary processes causing increased pressure. These are three in number, namely, (1) deprivation of normal nutrition in injured parts; (2) passage of water into these parts with consequent swelling; (3) the rigid inclosure of the brain causing this swelling in one region to markedly effect neighboring regions. The thromboses, extravasations and hemorrhages which accompany contusion impair the blood-supply of the injured region. Brain tissue deprived of blood undergoes chemical changes resulting in increased internal osmotic pressure and the passage of water into the tissue. The swelling thus produced compresses neighboring regions impairing the circulation and involving them in the process. This swelling is mainly produced by increased osmotic pressure which may be greater than the blood-pressure, thus preventing the blood from entering the cranium. Recovery from head injuries after pressure symptoms and the accumulation of fluid under the dura and in the ventricles is accounted for by the diffusion of the products of destruction from the tissues.

Precocious Maternity.—An extremely easy labor in a colored girl of eleven years with small pelvis is reported by L. M. Allen (*Maryland Med. Jour.*, Oct., 1901). The labor was attended with little apparent pain and was almost spontaneous, although preparations had been made for operative interference if necessary. The pelvic measurements were as follows: Interspinous, 22 cm.; intercristal, 21.5 cm.; right oblique, 18.5 cm.; left oblique, 18.5 cm.; external conjugate, 14.25 cm.; diagonal conjugate, 8.5 cm. The vagina was small. As a general rule a pelvis of 8 cm. true conjugate will allow labor to proceed either naturally or by version or forceps, but when below 8 cm., if the head cannot be made to engage, a major operation, either symphysiotomy or Cæsarian section, must be considered. Yet, as methods of measuring the pelvis give only approximate results, conservatism until Nature has had a good chance will save many a major operation.

Color Factor in the Anopheles Hunt.—Among the vast number of experiments which have been made with a view to exterminating the mosquito, those by George H. Nuttall (*Brit. Med. Jour.*, Sept. 14, 1901) seem of particular import and interest. Although for a long time it has been known that the *imagos*, particularly during the day, retire to dark and shady places, it would seem that the relation of the insects toward various colors has not yet received particular attention. Studies of their relation to white and black have been made by Austin, who noted that if the walls of the room were whitewashed with a dark dado, the insects invariably clustered on this, always avoiding white. Buchanan, in India, noted that the *Anopheles* always settle on the black coats hanging in the hospital wards, rather than on the white ones. Joly, writing from Madagascar, carries this observation further in reporting that mosquitoes were more attracted to black than to red or white sands. Brown clothes, he observed, attracted them less than garments of white. Madagascar natives have long known the attraction which black offers and hang black cloth from the rafters of their huts for the insects to collect upon. Yellow dogs he observed were less bitten than black ones, and in like manner the natives suffer more than the whites. In testing the influence of color on the *Anopheles*, a series of pasteboard boxes, each lined with a cloth of different color, was arranged near their breeding-place. Lest any outside factor might influence the settling of the mosquito, these boxes were caused to rotate daily. In the series of 17 observations, the number of *imagos* counted in the 17 different colored boxes varied from 108 for navy blue to none for yellow. Albeit the pale greys, greens, and blues did not collect at any time as many as 10. The practical bearing on this would seem to be that these lighter shades should be the color of all clothes in malarial districts. Nuttall also suggests that traps might well be constructed, the bait consisting of this seductive navy blue.

Bismuth Intoxication.—Symptoms of intoxication may be produced by either the internal or external administration of preparations of bismuth. A ten-per-cent. ointment of bismuth subnitrate was used by Dreesmann (*Berl. klin. Woch.*, Sept. 7, 1901) in dressing a burn of the second and third degree, involving the leg and thigh. Three weeks after beginning this treatment a black sediment appeared in the patient's urine. A severe stomatitis followed. On the gum-borders, anteriorly and posteriorly, a blue-black line formed. Enteric symptoms and albuminuria were both absent. Careful examination

of the drug used showed that there was no contamination with lead or other toxic substance. The patient's condition promptly improved when the bismuth dressings were discontinued and boric acid substituted. While bismuth intoxication is rare, when it does occur it presents a picture easily recognized; severe intoxications are therefore avoidable.

The Management of Eczema.—Perhaps there is no department of medicine so closely encircled by the mystic halo of miserable Christo-Mediæval pedantry, which after all, even to-day, masks and mars the bulk of our therapy as dermatology. That eczema, like any other skin disease, when cured, "strikes in," is even among the well-educated so firmly established a view, that it seems almost impossible to up-root it. HENRY WALDO (*Brit. Med. Jour.*, Sept. 21, 1901) outlines a number of common-sense points which cannot be too often repeated. Since the bulk of cases (see Kaposi and others) are not bacterial but irritative cleanliness is of paramount import. The part *must* be washed, but not with soap and water. Water harms by producing local cold through evaporation. A safe fluid to use is the juice of bran, oatmeal or starch, prepared from rainwater, and often it is well to tone it down by a dram of soda to the pint. The area must be washed in this once in twenty-four hours and immediately dried. Local rest is very important. Again, it is well to bear in mind the sympathetic relation which exists between the skin on opposite body sides, a hearty circulation produced in one side which may be healthy gives, by a keen provision of Nature, a similar condition in the opposite, whether diseased or not. Protection of the surface is of great import. Those remedies which yield the best results have been shown to be the best protectors. Internal treatment must not be ignored. Milk, blue pill, aperients, quinine, benzo-naphtol are of value. Much alcohol is bad, but Pye-Smith considers light ale not alone harmless but useful. As to diet it is well to recall Sir William Roberts' rule that any food which causes discomfort is not beneficial.

Apex Pneumonia.—Following an exhaustive résumé of the literature, E. F. CORDELL (*Maryland Med. Jour.*, Oct., 1901) concludes that lobar pneumonia affects the apex about one-third as frequently as the base, and the right apex three times as often as the left. Apex pneumonia is not rare in early life, but then the mortality when uncomplicated is almost *nil*. The general mortality of apex and basal forms is about the same. Involvement of both apices, or of one apex and the opposite base, is very rare and not especially fatal. Intemperance and hyperpyrexia do not increase the relative mortality at apex. Delirium is not more frequent, but is oftener seen in complicated cases than with basal pneumonia. Pericarditis is relatively more frequent, as is, also, otitis media, but there is no difference as regards icterus, hyperpyrexia, endocarditis, meningitis, pleurisy, diabetes or empyema. The apex form of pneumonia involves no tendency to eventuate in phthisis. Pericarditis is a fatal complication, and Bright's disease and bronchitis render the prognosis grave.

Double Stain for the Bacillus Diphtheriæ.—The bacillus diphtheriæ stains with all of the basic anilin dyes, and resists iodin in the Gram method. It is stained best with Löffler's alkaline blue. A stain which has the property of differentiating sharply the diagnostic features of the diphtheria bacillus is suggested by R. L. PITFIELD (*Univ. of Penn. Med. Bull.*, Sept. 1901). Three solutions are necessary: (*a*) Silver nitrate, gram 5; aqua destill., c.c. 5; sat. sol. (alcoholic) fuchsin, c.c. 3; (*b*) pyrogallic acid, gram 1; 10 per cent. sodium hydrate in water, c.c. 5; aqua destill., c.c. 10; (*c*) carbol fuchsin solution, drops 10; aqua destill., c.c. 10. Make a smear, fix with heat, pour on smear solution "*a*," boil a minute, wait a minute and then wash. Then pour on solution "*b*" and do the same; then wash and pour on "*c*" for a minute or two, wash, dry, and examine. The organisms appear delicately pink, of slightly uneven shades. Corresponding to the heaping of the protoplasm. At one or both ends, and afterward in the middle, brilliant shining black points appear, which stand out sharp and clear. The author believes that with this stain a rapid and certain diagnosis can be made without resort to culture media.

Nose and Throat in General Practice.—A physician should not be less expert in the use of the laryngoscope than in that of the stethoscope, writes JOHN HUNTER (*Canadian Jour. of Med. and Surg.*, Oct., 1901), for in personal discomfort, many nose and throat diseases are the "peers" of cardiac or pulmonary ones, and laryngeal and nasal diphtheria and tuberculosis stand in the front ranks of malignant diseases. The most interesting parts of the nasal cavity are the turbinated bones. Their porous character, and the large amount of erectile tissue in the thick layer of elastic mucous membrane surrounding them, make them reservoirs for storing blood, hence vulnerable to disease. The first evidences of disease in the nose are suppression or diminution of secretion of serum and swelling of the soft tissues. After twelve or twenty-four hours there is a profuse secretion of serum and mucus and an exudate of lymph and pus cells. Under certain conditions the mucous membrane may atrophy, the secretions diminish and become tenacious, hence may decompose and cause ozena. Adenoids give the clinical features of mouth-breathing, peculiar listless facial expression, mental dulness, impaired voice-production and articulation, deafness, reflex cough and deformity of the chest. Disease of the nasopharynx is often complicated by disease of the middle ear owing to the entrance of infectious germs into the Eustachian tube. The larynx shows the different forms of laryngitis, ulcers, tubercles, and tumors. Implication of the vocal cords impairs the voice. Enlarged tonsils and adenoids should always be removed early, otherwise the chest deformities, mental hebetude, etc., may become permanent. Local

treatment of the nasopharynx consists of the spray or douche of boric acid, sulphocarbolate of soda, etc., in solution, or of inhalations of hot, dry, moist or medicated air. When using a douche the mouth must be kept open, and no attempt made to swallow or cough, lest some infectious matter be carried into the Eustachian tubes. In cases with excessive discharge and infiltrated tissues, a dry, bracing atmosphere is best, but where the tissues are irritable, reflexes exaggerated, or the secretions diminished and thickened, an equable, warm, moist climate is preferable.

Conjunctivitis from X-Rays.—The continued use of the X-rays has been found to cause various disturbances in animal tissues besides simple burns, but severe irritation of a peculiar kind is probably responsible for it all. J. W. Sherer (*N. Y. Med. Jour.*, Sept. 21, 1901) reports the case of a physician who had been daily exposed to the action of X-rays for three years and a half, having made use of these rays in the treatment of carcinomata. A desquamative dermatitis of the exposed parts of the face developed accompanied by bronzing and a little later both lower lids became thickened and the eyelashes and eyebrows were lost. A distinct retinitis also appeared, presumably due to the same cause. The conjunctivitis was limited to the lower eyelids. All these lesions cleared up readily under treatment and removal of the cause. Of three cases treated by this physician for carcinoma of the ocular region only one showed irritation of the eye, although each received about seventy-five treatments.

Gonotoxin and Immunity.—On account of the insusceptibility of most animals to the gonococcus infection, almost insurmountable difficulties have arisen in the attempt to produce an antitoxin serum by the ordinary methods. The goat seems, however, to be susceptible to this poison and De Christmas is said to have produced immunity in this animal. J. R. Eastman (*N. Y. Med. Jour.*, Sept. 28, 1901) in a discussion upon the gonococcus and its toxin, states he believes a certain degree of natural immunity exists in such individuals as have been cured of an attack of acute gonorrhea. Very rarely an old roué appears with an acute gonorrhea and when he presents a urethritis it is generally an old relapsing case. Seventy-five per cent. of cases treated occur in men under twenty-five," says I. N. Bloom. Children are very susceptible to the gonococcus infection, and as age advances fresh infections become rarer. It is believed that a gonorrheal urethritis, once cured, confers to some degree an immunity against a subsequent attack.

Diagnosis of Brain Diseases.—Many important suggestions in the diagnosis of brain lesions are given by J. F. Eskridge (*N. Y. Med. Jour.*, Sept. 28, 1901). A change in the character of the respiration, rather than in its frequency, is sometimes the first positive symptom of organic intracranial disease, especially of tuberculous meningitis. A respiration that is more frequent while the patient is asleep or unconscious than while awake is very strong evidence of organic disease. Apoplexy due to hemorrhage is attended with greater disturbance of temperature soon after its occurrence than when due to thrombus or embolus. There is usually, in cases of hemorrhage, a rise of 2° to 3° F. within six or eight hours, a little higher on the paralyzed side, and gradually coming down at the end of a week or more. In embolus or thrombus cases there is no disturbance of temperature for two days or more, except in very severe cases. Considerable rise in temperature at the end of two to four days is significant of thrombus or embolus with extensive softening. A persistent higher temperature on the paralyzed side indicates softening or inflammation and renders the prognosis grave.

Prophylaxis of Tuberculosis.—Since the positive proof of the existence of the tubercle bacillus was made known, great stress has been laid upon the fact that it is a contagious disease and laws have been enacted based upon the supposition that the greatest danger in regard to consumption arises from infection. J. Kucher (*Med. Rec.*, Sept. 28, 1901) believes that too much stress is laid upon this point and people are led to forget that the tubercle bacillus must have a suitable soil to work upon and therefore the observance of ordinary hygienic rules of life is frequently far more important in preventing the spread of tuberculosis than any attempt which may be made to avoid infection. If boards of health would concentrate their attention upon regulations of undisputable merit, which are at the same time practicable, and teach people how to live more healthful and hygienic lives it is thought that more good could be done. It must be realized that the tubercle bacillus is ubiquitous and cannot be avoided. It is harmless unless it falls upon favorable soil and the best way to escape it is to fortify the body by a sufficient amount of sunlight and good air, together with proper food and healthful work.

Puerperal Sepsis.—The cause of puerperal sepsis is to be found in some contamination introduced from without which in the congested uterus finds a ready means of propagation on blood-coagula and other dead material. A. Hegar (*Münch. med. Woch.*, Sept. 17, 1901) describes the end result as follows: Either a general peritonitis sets in or a circumscribed focus forms which may involve the pelvic peritoneum or may be retroperitoneal, sometimes extending up through the diaphragm and setting up secondarily a pleuritis or pericarditis. It is important to know that in the cases of pelvic abscess the peritoneum is always involved primarily, the tubes secondarily. A third set of cases is that where the vessels of the uterus are chiefly affected and thrombi with secondary emboli form. All these pathological processes show themselves by a septic fever curve, rapid pulse and respiration, slight cyanosis, dry tongue and benumbed sensorium. Sapremic fever can usually be readily differentiated; it begins early, lasts from one to four days, rarely exceeds 38.5° C., and with it there is a relatively slow pulse, moist tongue and clear mind, while the physical examination is negative.

The therapy of puerperal sepsis is still unsatisfactory and little is to be expected from antistreptococcic sera. The performance of hysterectomy has the disadvantage that one never can tell if the process is still confined to the uterus, The author believes in permanent drainage with irrigation of chlorine water (⅛-¼ liter to one liter of lukewarm water) to be repeated every one to two hours by means of a glass cannula connected with a rubber tube and funnel.

Treatment of Seasickness.—Arguing upon the close anatomical relation which exists between the vomiting and respiratory centers on the floor of the fourth ventricle, R. HEINZ (*Münch. med. Woch.*, Sept. 17, 1901) recommends that if the nausea indicative of beginning seasickness sets in, deep inspiratory movements be made to prevent the vomiting. Animal experiments and observations on his own person have convinced him of the practical value of this procedure.

Renal Diabetes.—That a diabetes may develop in diseases of the kidney similar to the experimental phloridzin diabetes is stated in most works on diabetes. H. LUETHJE (*Münch. med. Woch.*, Sept. 17, 1901) says, however, that before this diagnosis can be made the following must hold true. (1) Absence of glycosuria before the renal disturbance; (2) synchronous appearance of glycosuria and renal disease; (3) absence of relationship between the kind of food taken and the amount of sugar excreted; (4) diminution of the amount of sugar contained in the blood. One case has come under the author's observation where the diabetes followed an ascending pyelonephritis, gonococcic in origin.

Hand Disinfection.—The extended experiments of TH. PAUL and O. SARWEY (*Münch. med. Woch.*, Sept. 3, 10, 17, 1901) lead them to believe that even with the aid of the most poisonous mercury compounds it is absolutely impossible to render the hands germ-free. The number of bacteria remains large, no matter whether sublimate in aqueous solution be combined with alcohol, or the hands are first rendered fat-free with bolus-paste, or other solvents such as acetone or methyl-alcohol be used, or the sublimate be combined with ointments, or finally if complex mercury-salts be used. As long as no better methods are available, sublimate can, however not be replaced in the surgical disinfection of the hands, since with it the best possible results are obtained.

Etiology of Rectal Polypi.—Of benign polypi in children there are two forms, writes FRANCIS HUBER (*Archives of Pediatrics*, Sept., 1901), the soft gelatinous, composed of the elements of the mucous membrane, and the hard or fibrous, representing mucous membrane supplemented by the connective tissue beneath. Rectal polypi usually originate an inch or so from the anus. The soft may be villous, pedunculated, and from the size of a pea to that of a Concord grape, or glandular or cystic with a short and thick pedicle. Both bleed freely. Polypi are usually single, but may be multiple. The author has observed that rectal polypi occur only in those who at the same time showed evidences of lymphoid hypertrophies in the nasopharynx with other manifestations of the status lymphaticus. The pathology is identical with that of adenoids. Polypi are often not discovered, though there may be slight hemorrhage from the rectum, pruritis, fissures, or mucorrhea. In the lymphatic dyscrasia, diarrhea, constipation or other local condition would tend to increase the already large follicles of the rectum, and the expulsive action of the intestine would tend to produce from them a polypus.

Classification of Insanity.—The following five groups of mental affections, F. X. DERCUM (*Jour. of Nervous and Mental Diseases*, Sept., 1901) regards as elemental forms of insanity: (1) Delirium (simple febrile, specific febrile or *delirium grave*, and afebrile), confusion, stupor; (2) melancholia, mania, circular insanity; (3) paranoia; (4) neurasthenic insanities; (5) dementia. The febrile deliria accompany various acute infections, the exanthemata, etc., but *delirium grave* is unaccompanied by any signs of visceral or surface involvements. Afebrile deliria are met with following acute exanthemata, or various intoxications (lead, alcohol), and after trauma or shock. Confusion is a less active and more prolonged condition due to profound and persistent exhaustion and toxin-absorption. There is mental hebetude, but not the cerebral activity indicated by delirium. When confusion proceeds until there is much loss of appreciation of the surroundings, it becomes stupor. In these affections the emotions have no influence, and heredity little if any. In melancholia, mania and circular insanity we have, however, a closely-related group in which heredity and the emotional play an important part. In paranoia we find a history of prolonged mental depression with gradual evolution of delusions of persecution, and finally expansive delusions. The delusions are systematized and persistent. The mania-melancholia condition is intermittent. Neurasthenia implies ready bodily and mental exhaustion and deficient self-control. Dementia presents the signs of mental loss, with failure of the mental faculties, such as memory. The insanities of puberty are the precocious dementias, (1) hebephrenia, marked by elements of depression and expansion; (2) katatonia, with expansion more pronounced, and certain motor disturbances, spasms of muscles, cataleptoid attitudes, automatism, etc.; and (3) marked and well-defined phases of depression and expansion with well-formed delusions more or less systematized. Delirium, confusion and stupor may be met with at any age, mania and melancholia belong to early adult life, and paranoia, the chronic delusional insanity, appears after thirty-five years of age; a persistent melancholia is met with in the middle-aged. The insanities of old age, the senile dementias, may take the form of simple mental loss, of dementia with confusion, delirium or stupor, or of so-called senile paranoia, a dementia with systematized delusions. From the medical point of view, all the mental disor-

ders resulting from the infections, intoxications, diatheses, visceral diseases, nervous diseases, pregnancy, the puerperium and lactation belong to groups one and five. Mania and melancholia never result from these causes, but are diseases primarily of the nervous system, and are largely hereditary. Likewise paranoia and neurasthenia bear no relation to internal diseases, but are favored by persistent depression of nutrition, or anything that will cause degenerative changes in the nervous system.

THERAPEUTIC HINTS.

Kumyss.—Heat two quarts of milk to 100° F., or Pasteurize and cool to 100° F. Dissolve one-third of a yeast-cake in two tablespoonfuls of the milk, boil two tablespoonfuls of sugar with three tablespoonfuls of cold water, mix all together and bottle at once. Cork firmly and stand in a warm (70° F.) place over night. Next morning place the bottles carefully on their sides in a cool place for twenty-four hours. Open with a tap, or use ordinary beer-bottles.—H. V. Sachse in *"How to Cook for the Sick."*

Acute Rheumatism.—Bile should be of alkaline reaction, but in rheumatism it is strongly acid, probably on account of biliary stasis and accumulation of uric acid, therefore F. L. Satterlee (in "Rheumatism and Gout") prescribes a cholagogue at the outset. A good formula is:

℞ Euonymin .....0.015 (gr. ¼)
Podophyllin
Aloin aa .....0.008 (gr. ⅛)
Sig. One tablet morning and night as required.

Next alkalies must be given, preferably the sodium salts. The following is effective and well borne by the stomach:

℞ Lithii benzoat.....2.0 (ʒss)
Sodii bromid
Potass. carbonat. aa.. 8.0 (ʒij)
Potass. acetat.....45.0 (ʒiss)
Sodii phosphat.....15.0 (ʒss)
Syr. zingiberis
Aq. menth. pip. aa q. s.
ad .....180.0 (ʒvj)

M. et Sig. Two to four drams in water, every four to six hours, after food. Or sodium bicarbonate or phosphate may be given or

℞ Potass. bicarb. .....12.0 (ʒiij)
Aq. destillat.....240.0 (ʒviij)

M. et Sig.: One dram to half an ounce of fresh lemon juice, to be taken while effervescing. The alkalies should be kept up until the sweat and urine show no acid reaction to blue litmus. Then a small dose will suffice to maintain the alkalinization of the system. The writer never employs the salicylates, as these tend to produce relapses, gastric and cerebral disturbances, cardiac depression, obliteration of the first sound of the heart, etc. Fever may be met with antipyrin, antifebrin or phenacetin, used, however, with caution. Quinine is worse than useless. These antipyretics are also analgesic, but morphine may be needed. If natural and painless sleep is urgently indicated, the following may be given at one dose:

℞ Morph. sulph.....0.015 (gr. ¼)
Potass. bromid. ....2.0 (gr. xxx)
Chloral. hydrat.....1.3 (gr. xx)
Syr. aurant. cort....8.0 (ʒij)
Aquæ, ad.....30.0 (ʒi)

Of mineral waters, Vichy is very serviceable as a vehicle, and Rubinat Llorach to act on the liver.

When the acute symptoms have subsided, the heart must be toned, and the following mixtures are suggested:

℞ Spt. ammon. aromat. 90.0 (ʒiij)
Ammon. carb..... 4.0 (ʒi)
Tinct. cardamom.....30.0 (ʒi)
Tinct. nucis vom.....12.0 (ʒiij)

M. et Sig.: One dram in water, t.i.d., or, as general tonics,

℞ Tinct. ferri chlorid...15.0 (ʒss)
Tinct. nucis vom.
Acid. phosphor. dil. aa 8.0 (ʒij)
Syr. aurant. cort.....30.0 (ʒi)
Elix. calisayæ.....60.0 (ʒij)

M. et Sig.: One dram in water t.i.d., half an hour before meals, or

℞ Cinchona flav. cort... 12.0 (ʒiij)
Aq. bullient.....150.0 (ʒv)
ft. decoct. et adde
Ac. hydrochlor..... 1.3 (♏xx)
Syr. aurant. cort.... 30.0 (ʒi)
Sig.: One tablespoonful in water t.i.d.

The excessive thirst may be met with water or lemonade. The diet consists of milk, chicken or clam broths, or vegetable soups. The return to solid food should begin with white meat and vegetables, as asparagus and celery.

One of the best topical applications is:

℞ Tinct. aconit. rad.
Tinct. arnicæ aa.....15.0 (ʒss)
Chloroformis .....30.0 (ʒi)
Tinct. saponis camph. 60.0 (ʒij)

M. et Sig: Apply on lint, or rub joint and cover with cotton. When the inflammation determines great effusion into a joint, threatening its integrity, blisters are efficacious.

Insomnia.—In summing up the influence of hypnotics, Mitchell Bruce (in *"Materia Medica and Therapeutics"*) advises that full advantage be taken of the indirect group. Bromides are indicated when the cerebral circulation is excited by overwork; and chloral may be combined with it. Pain or mental distress require opium. Alcohol at bedtime may be invaluable. In every instance the time of administration of hypnotics must be carefully ordered. It must never be forgotten that the narcotics, such as opium and chloral, are powerful depressants of the respiration, circulation and excretion, and may thus produce disastrous results whilst they afford the desired sleep.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SMITH ELY JELLIFFE, A.M., M.D., Ph.D., Editor,
No. 111 FIFTH AVENUE, NEW YORK.

Subscription Price, including postage in U. S. and Canada

PER ANNUM IN ADVANCE	$4.00
SINGLE COPIES	.10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, OCTOBER 12, 1901.

POLITICS AND HEALTH DEPARTMENTS.

NEW YORK is not the only city in which the officials hold office for other reasons than their health. Philadelphians are wondering what excuse their Board of Health has for its superfluous existence, in the presence of such death-familiar leaders as Mayor Ashbridge and Col. Good. The Mayor having twice held the office of coroner, and Col. Good having been his undertaker before he became Health Officer, they both seem to have too keen an eye to business, to wantonly cut down the mortality of the city by enforcing even the most simple and necessary sanitary measures.

The recommendations of leading men in the study of tuberculosis, that every case of consumption should be registered, and whenever necessary be followed up by the Board of Health, have never gotten beyond the paper they were written on, for the reason that the Mayor does not believe that tuberculosis is a contagious disease. The Mayor admits that he vetoed the resolutions which his own Board of Health had passed, giving as a reason, lack of funds to carry out the measures. New York and Boston and Brooklyn have shown that the expense amounts to about 70 cents per case, and could be covered by about $1,000 a year, and that the liability to contagion is perceptibly diminished by such measures. But the Mayor evidently felt that this was a case for him to use the discretion of ignorance, and the discrimination of prejudice, and so refused to notify the physicians of the city that they should report all cases of tuberculosis, and refused to register those cases that were reported by the chief medical inspector of the city.

The spitting nuisance having excited the wrath of citizens and physicians to the point of action, was formally considered by the Civic Club and the Traction Company of Philadelphia, and steps were taken to procure an ordinance against spitting in public places and corridors. But when the enthusiasm of the anti-spitters reached the Board of Health it met a stone wall of indifference. Possibly the Mayor of Philadelphia believes in spitting as heartily as he disbelieves in the contagiousness of consumption. Possibly he can devise more efficacious ways of spending the public money. Possibly he feels, as do certain Tammany leaders, that he has the dubious honor of his party to uphold, and fears to sink to the level of a mere reformer.

At all events Philadelphia's fame as a center of medical science, the reputation of her men, her hospitals and her literature are but as a feather in the pan when measured with the gold bags which her doughty Mayor reserves for political purposes.

PRACTICAL PROBLEMS IN TUBERCULOSIS.

THE control of the spread of tuberculosis is the most important problem which confronts the medical profession of to-day. Although the researches of a large number of experimental investigators and the practical deductions of countless numbers of clinicians have been brought to bear upon this question, we are forced to admit that, while final success seems assured, the ultimate lines along which this conflict is to be fought have not been as yet laid down with distinctness.

It cannot be denied that from a practical standpoint the most perplexing problem in regard to this disease with which the clinician is to-day brought face to face is the proper and judicious handling of the actual cases of tuberculosis which come under his care. This fact should not be lost to view by those who are at work upon the tuberculosis question. In the absence of any

specific medication which can successfully be applied to this condition and the uncertainty of the result of any and all symptomatic methods of treatment, this problem becomes doubly critical, nor is the adoption of a proper therapeusis the only difficulty. Not less important is the institution of advantageous hygienic measures and above all the advisability of counseling change of residence in the existing circumstances which surround each individual case. When once the diagnosis of tuberculosis is established, the latter becomes one of the most anxious questions to be answered, as it is far reaching in scope, involving the domestic, financial and commercial interests of the patient and those connected with him.

The ability of the physician to deal judiciously with these correlated questions determines oftentimes not only the future outcome but also the personal comfort of the patient and the subsequent fortunes of those related to him. Any information that will contribute to wise decisions is doubly welcomed.

For an intelligent understanding of the conditions and as a basis of wise counsel at least two factors need careful consideration: (1) The virulence of the micro-organisms with which the patient is infected; (2) the degree of resistance which the patient possesses to such infection. Scientific investigation has thus far failed to produce any specific criteria by which the degree of resistance to an existing infection may be definitely established. For a determination of this factor, therefore, we are limited to the clinical observation of the case and provided the virulency of the infecting organism can be reasonably established, such observations are of value, the duration of the infection and the extent of the lesions furnishing valuable data.

The determination of the first of these factors, however, is most important as the virulency of the invading organism often decides the subsequent course of the disease in human beings. Heretofore but little work has been done with the bacillus tuberculosis. Dr. A. J. Lartigau (*Jour Med. Research,* July, 1901) reports the study of this organism in 19 cases of human tuberculosis, 8 of which were scrofulous lymphadenitis, 9 pulmonary tuberculosis and 2 tuberculous bone lesions. His object was to ascertain, if possible, the variations in virulence among tubercle bacilli encountered in different tuberculous lesions in man and the relation of this virulence to the clinical and morphological types of the disease. His work was carried on by the inoculation of the tuberculous material into a series of guinea-pigs and rabbits which, after various periods of time, were submitted to bacteriological and pathological examination. The dosage of the inoculated material was accurately regulated by a careful technic.

He shows that the inoculation of the bacillus tuberculosis from different human sources induces various degrees of tissue reaction in these animals which, if the investigations are carried on under proper precautions, indicates a variation in the virulence of the organism used. In scrofulous adenitis the bacilli were usually of low virulence, but in some cases they may be of marked activity, in which case the process is apt to extend to other tissues. Tubercle bacilli of widely different virulence may be present in any one of the various tuberculous lesions. So-called healed tuberculosis of the lung may contain virulent or attenuated bacilli. An individual already infected with an organism of slight virulence may undergo a fresh infection with extremely virulent bacilli and chronic tuberculous bone lesions may contain bacilli of both low and high virulence.

The determination of the degree of virulence of organisms pathogenic for man by a study of their effect upon research animals has been employed with respect to many bacteria, but no special study along these lines has been hitherto attempted with respect to the bacillus tuberculosis. From a careful consideration of Dr. Lartigau's work, it would seem as if the time was at hand when the laboratory is to render more aid to the physician in regard to this disease than the mere diagnosis of the condition. Further research along similar lines promises to give results of value which may be utilized in the treatment of individual cases.

COMMERCIALISM IN MEDICINE.

It has recently been said that, while law has become a business and other professional callings are moving in the same direction, the medical profession has during the past fifty years steadily grown away from commercialism. By this statement we are to understand, not that the physicians of to-day have retrograded in sound business policy, but that the ascendency of what is known as "sharp practice" in the commercial world over the professional duties which form the keynote of medical practice has been avoided.

Assuming that this statement is correct, and as applied to the profession in its entirety it undoubtedly is, there would seem to be implied a libel on the motives of those members of the profession who have gone before, placing them in a less favorable light than the facts warrant. In the last analysis, however, it will be seen that this implication is more apparent than real. If there is any reason why the physicians of to-day are less commercial than those of a half-century ago, it is because of the tremendously increased knowledge in the medical sciences which has more and more drawn their attention from things financial to scientific considerations, so that those who would be sure of ultimate success have had less opportunity to commercialize themselves than did their predecessors. It will be seen, therefore, that the primary object in drawing away from commercialism has been partially one of self-advancement rather than wholly one of philanthropic generosity.

This statement is no slur on the medical profession of to-day for it is a historic fact that the spirit which has very largely actuated scientific leaders in all ages has in the vast majority of cases been this same indomitable desire for individual success.

In regard to the profession of medicine, it has somewhat been the practice in the past, and the same unfortunately prevails in some quarters at the present, to ascribe a very considerable degree of success to that fortunate combination of circumstances known as "good luck" when added to the characteristics of a pleasing personality, the reputation of always being a busy man, and sharp business methods. While in years gone by these possessions may have contributed in a fair degree to personal advancement, the keen-sighted observer, thoroughly conversant with existing conditions cannot fail to observe that the value of these qualifications has been steadily relegated to the rear and that accurate and scientific knowledge along all lines of the allied medical sciences has been the chief factor of success with the preeminent medical men of to-day and must increase in importance for those who are to attain success in the future.

We do not intend to depreciate the value of sound business methods as applied to one's professional career, but to hold that those who are to stand in the front ranks of the future must be essentially physicians in all that the name implies and be further removed from what may be known as commercialism than those who have preceded. It is to be remembered that this conception does not prevent one from utilizing all the known legitimate means for making a livelihood which are open to the medical profession and that such may be used with impunity in so far as they do not conflict with the main object in view nor seriously interfere with a steady progress toward the ultimate goal, but the danger that such means should become to be regarded as the main factors of success must be constantly averted.

It is to be admitted that in certain sections, especially in large cities, there has been evidenced, particularly during the past ten or fifteen years, a tendency on the part of a very limited number of the profession toward commercialism, thus, by their methods, placing themselves on a level with those pursuing ordinary avocations. It should be remembered that by so doing they have virtually withdrawn from the profession and entered into a business on a business basis, submitting themselves to the ordinary laws of commercial pursuits. Observation will show that whatever financial success may have attended their course even this is short-lived from the very fact that the goods which they purport to sell are not marketable in a commercial sense beyond a very limited field. That this evil will always exist is to be expected, but that it will ever become a factor sufficient to degrade the profession in its entirety cannot be comprehended, for the vast majority of those who enter medical practice will always be keen enough to see that genuine success does not lie along these lines and that satisfactory prosperity in the medical profession is incompatible with commercialism in any form.

THE OPENING OF THE NEW TUFTS MEDICAL SCHOOL IN BOSTON.

On the third of the present month the new building of Tufts College Medical School was formally opened. The building is designed to accommodate both the medical and dental departments, the view taken by the president and trustees being that dentistry, now that it has come to be recognized as a serious pursuit of professional grade, should be maintained at the same dignified level as medicine. And it is thought that by bringing the two faculties under one roof the very best opportunities will be afforded to the student of dentistry to keep properly abreast with the advances which are constantly taking place in anatomical and physiological science.

The soundness of this point of view is very obvious. Even at the present day the notion is widespread in some parts of the profession that the chief requirements for a dentist are—as President Capen quotes them in his opening address—a good eye and deft fingers. On account of this very view we fear that many dental curricula are constructed mainly with the view to the development of eye and fingers, in other words to the training of good mechanics without very much thought to the character of the field in which these mechanics are going to do their work. Now if we consider what a tremendously important factor the teeth are in the maintenance of the entire economy in a healthy condition, the wisdom of Tufts in endeavoring to place her dental students in an atmosphere calculated to stimulate to the highest degree a desire for a thorough knowledge of the chemistry, physiology and anatomy of their chosen branch, is at once apparent.

Apart from this attainment of a specific desire Tufts has, by thus starting out on a larger and sounder basis, accomplished something of even greater significance to medical advance. She has started a new epoch in the history of medical education in Boston. By this we mean she has placed herself in a position to cope with her older and better-known rival, Harvard. The results of such a step as this cannot, we believe, fail to have a beneficial reaction upon both colleges. It tends tremendously to stimulate the teachers in both to do their uttermost, those of the one to gain prestige, those of the other to maintain it. And such rivalry is good for any medical center. To borrow a commercial expression, competition is the life of trade. That it is not wholly bad for science is strongly evidenced by the zeal and activity which mark the work that is done in medical educational circles in Philadelphia—a city where rivalry among medical colleges reaches as high a point as in any city in the country. Here each rival school is stimulated to do its utmost for the students whom it attracts, the feeling being that no amount of prestige gained by age or otherwise can exempt from the closest attention to the exigencies of modern medical teaching. One striking result of all this activity is the higher and higher standard of excellence which these schools are attaining year by year.

Boston is certainly large enough to maintain two medical schools of the first excellence and it behooves Tufts, now that she has taken a fair start, to leave nothing undone that will tend to add the proper sort of cubits to the stature of her fame—cubits of high ideals, of scientific broad-mindedness and of simple humanity. We wish her every success.

ECHOES AND NEWS.

NEW YORK.

Reception to Dr. Waldeyer.—The German Medical Society of the City of New York purpose to celebrate the presence of Professor Waldeyer in the United States by a dinner on Saturday, October 25th, in New York City.

$25,000 for University Medical School.—The sum of $25,000, Chancellor MacCracken announced at Monday's meeting of the New York University Council, has been given to the Medical School by one who wishes his name withheld. The Chancellor reported that the university is more prosperous than for a long time.

The Kings County Medical Association.—A stated meeting of the association was held in Wurzler's Building, 315 Washington street, third floor, on Tuesday evening, October 8th. Dr. Henry H. Morton presented a Case of Vesical Calculus, with Specimen, and also A Dissection of the Seminal Vesicles; Dr. Joseph F. Todd reported on five cases of puerperal eclampsia. Dr. Charles Dwight Napier read the paper of the evening on The Treatment of Congenital Club-foot. It was discussed by Drs. Walter C. Wood and J. M. Clayland.

To Ventilate Tunnel Cabins.—The New York Central and Hudson River Railroad last week applied to the Park Department for permission to open ground at four different points along its Park avenue tunnel for the purpose of laying ventilation pipes from the underground signal cabins at Fifty-ninth, Seventy-second, Eighty-sixth and Ninety-sixth streets. This is the first direct step taken by the road to comply with the Health Board's orders to improve the ventilation of the tunnel. The cabins are to receive a supply of outside air by means of 12-inch cast iron pipes ending in overground ventilation caps.

A Health Board Boomerang.—Some of the property owners living in Park avenue have protested to the Health Board against the changes proposed in the New York Central's tunnel. They assert that if the tunnel's present brick walls are replaced by steel girders and the roof is left more open for ventilation the smoke and fumes at present confined to the tunnel will enter their houses, endangering the health of the occupants. They are about to get up a petition to the board. "Of course these people think they have a grievance," said President Sexton of the Health Board yesterday, "but they are mistaken in their belief that

their houses will be filled with smoke; soft coal is not used in the tunnel. There may be a few cinders, but that can't be helped. It is quite impossible to please every one. The change in the tunnel is absolutely necessary, and will be made."

Mortality in the State.—The bulletin of the State Board of Health for the month of August shows that the mortality was 11,000, or 1,300 less than in July, which was excessive. The only material decrease from July, however, was in deaths from accident and violence, to which insolation, or heat stroke, added 1,300 deaths. This was the cause of very few deaths during August. There were five deaths from lightning stroke and fifty-four from drowning. Acute diarrheal diseases increased the mortality over July, causing 23 per cent. of all deaths, as against 18 per cent. in July. This increase is seen in all the sanitary districts, but is relatively greater in rural than in the urban districts. This mortality is, however, largely urban. Deaths from typhoid fever increased from July in all the districts, diphtheria as a cause increased to a small extent, and whooping cough, as always, showed its largest mortality in August in this State. All local diseases caused fewer deaths. Deaths from acute respiratory diseases fell to 500, which is low. Two hundred and eighty of the deaths were from pneumonia. Outside of New York City there were 210 deaths from Bright's disease. Smallpox caused forty deaths, all in the maritime district.

Preliminary Program of the Eighteenth Annual Meeting of the New York State Medical Association.—The program of the meeting of this association is just announced. The reading of papers will begin Tuesday, October 22d, as follows: The Correction of Deformities following Osteitis of the Knee, by Wisner R. Townsend of New York; Echinococcus Disease in North America, by Irving P. Lyon of Buffalo; Appendiceal Fistula, by John B. Deaver of Philadelphia; The Clinical Course of Cancers, by Albert E. Woehnert of Buffalo; The Present Status of the Infectious Theory of Malignant Neoplasms, by George Blumer of Albany; The Estimation of the Malignancy of Tumors with Reference to the Reported Cures of the Disease, by James Ewing of New York; The Treatment of Sarcoma by Toxin Injections, by William B. Coley of New York; The Treatment of Carcinomatous Growths by Caustics, by Andrew R. Robinson of New York; The Surgical Treatment of Cancer, by Francis W. Murray of New York; Malignant Disease of the Nose and Accessory Cavities, by Joseph H. Gibb of Philadelphia; Intrathoracic Growths, by Alexander Lambert of New York; Cancer of the Large Intestine, by James P. Tuttle of New York; Malignant Disease of the Penis, by Henry H. Morton of Brooklyn; Malignant Disease of the Uterus, by William M. Polk of New York; The Daily Medical Inspection of Schools, by Frederic William Loughran of New York; Perforation of Gastric Ulcer, with report of a case successfully operated upon sixty hours after perforation, by Lucius W. Hotchkiss of New York; Alcohol as a Therapeutic Agent at the beginning of the Twentieth Century, by Frank Wellington Dennis of Unionville; The Diagnosis and Management of Pelvic Inflammation, by A. Brothers of New York; Skin Diseases of special interest, illustrated by the Stereopticon, by Grover W. Wendé of Buffalo. Collation.

Third Day, Wednesday, October 23d. *Symposium on Arteriosclerosis.* Arteriosclerosis; Importance, Definition, Etiology and Symptomatology, by Charles E. Nammack of New York; Retinal Findings in Disorders of General Nutrition, by L. A. W. Alleman of Brooklyn; Cardiac Manifestations of Arteriosclerosis, by DeLancey Rochester of Buffalo; Management and Therapeutics of Arteriosclerosis, by Egbert Le Fevre of New York; Blood Examination from the Standpoint of the General Practitioner, by Frank W. Higgins of Cortland; Surgical Malposition of the Gall Bladder, by E. D. Ferguson of Troy. President's Address: Comments on some New Surgical Methods, by John A. Wyeth of New York.

Iodophilia, by Richard C. Cabot of Boston; Laboratory Differential Diagnosis in Surgery, by Simon Flexner of Philadelphia; Modifications in the Methods of Operative Surgery resulting from Laboratory Research, by Joseph D. Bryant of New York; The Use of the Pneumatic Cabinet in the Treatment of Diseases of the Heart, by Charles E. Quimby of New York; Gunshot Wounds of the Hip-joint by Reduced Caliber Projectiles, by Maj. L. A. LaGardi of Washington, D. C.; Asthma of Blood Origin and not Nerve or Reflex, by G. N. Jack of Depew; Conservative Surgery in the Treatment of Tubercular Glands of the Neck, by Parker Syms of New York; A Reconsideration of the Pathogenesis of Concomitant Strabismus, by Alvin A. Hubbell of Buffalo; Acne, by Edmund L. Cocks of New York.

Fourth Day, Thursday, October 24th. Differential Blood Count in Fractures, by Wm. G. Le Boutillier of New York; Prostatic Obstruction to Urination. Its Remedy by Enucleation of the Diseased Parts, by J. W. S. Gouley of New York; Typhoid Cholecystitis, with Report of Cases, by Charles G. Stockton of Buffalo, in conjunction with Albert T. Lytle of Buffalo; Uterine Prolapse, by Frederick Holme Wiggin of New York; What Percentage of Rheumatic and Gouty Patients Develop fatal Pulmonary Phthisis? by Thomas F. Reilly of New York; The Diagnosis of Mitral Stenosis, by H. C. Buswell of Buffalo; Resection of the Cervical Sympathetic in the Treatment of Glaucoma; its present status, by Wilbur B. Marple of New York; A Durham-tube in the Right Bronchus, by E. D. Ferguson of Troy; Indications for Treatment in Uterine Myomata, by George Tucker Harrison of New York; Brief Comments on the Materia

Medica, Pharmacy and Therapeutics of the year ending July 1, 1901, by Edward H. Squibb of Brooklyn.

New York State Association.—The Trunk Association has agreed that persons from points in New York State who pay one full fare of 75 cents or upwards, visiting New York City at the time of meeting, shall be returned at one-third of the fare by the route traveled. Certificates must be obtained from ticket agent at starting point (or nearest station issuing through tickets to place of meeting) and be deposited with the Secretary of the Committee on Arrangements as soon as the members arrive at the Academy of Medicine. It must be understood that the reduction is contingent on an attendance of not less than 100 persons holding certificates, showing payment of full first-class fare. If the necessary minimum is in attendance, and the certificates are properly validated, the holders will be entitled to the reduced return fare as late as October 28th.

PHILADELPHIA.

Dr. Mitchell's New Book.—Philadelphia's noted physician and author, Dr. S. Weir Mitchell, has just added another to the list of popular books from his pen. The new novel "Circumstance"—a picture of American and Philadelphia society—bids fair to add luster to the author's already enviable reputation as a writer.

Reception to Dr. Hayhurst.—A reception was tendered October 1st by the Woman's Medical College to Dr. Susan Hayhurst, who for 25 years has been pharmacist of the hospital. Dr. Hayhurst graduated in medicine in 1857 and afterward became the first woman to graduate in pharmacy in this city, that degree being obtained in 1883.

Pay Hospital for Contagious Diseases.—An entertainment for the benefit of the fund for this proposed hospital is to be held in the Academy of Music November 11th to 16th. The suggestion has been made that the institution be called the "McKinley Memorial Hospital." The suggestion is meeting with much favor among physicians and others interested in the undertaking.

Opening of Medical Schools.—The various medical schools of the city began the session of 1901-02 on October 1st. The opening address at the Medico-Chirurgical was delivered by Dr. John C. Heisler, Professor of Anatomy. The exercises at Jefferson were opened by an address by Dr. J. Chalmers Da Costa, Professor of Surgery. Dr. Da Costa will lecture to senior students and hold the Wednesday clinics in the place of Dr. W. W. Keen who is now in Japan on his vacation trip around the world. Provost Harrison delivered the introductory address at the University of Pennsylvania. Several changes in the faculty were announced. Dr. M. H. Fussell has been made Assistant Professor of Medicine, Dr. Thomas R. Neilson Assistant Professor of Genito-Urinary Diseases, and Dr. E. H. Gregory, Jr., Demonstrator of Anatomy. Dr. Horatio C. Wood has resigned the clinical professorship of nervous diseases but retains the professorship of materia medica, pharmacy, and general therapeutics. On account of ill health he has been granted one year's leave of absence during which Dr. Frederick A. Packard will lecture on applied therapeutics and Dr. H. C. Wood, Jr., on the physiological action of drugs. The Freshman class is reported to be nearly twice as large as that of last year.

Present Status of Serum-Therapy.—Under the title of "The New Weapon for Fighting off Disease" Dr. Joseph McFarland, Professor of Pathology and Bacteriology at the Medico-Chirurgical College, contributes an article to a late issue of the Saturday evening *Post*. Dr. McFarland writes of immunity, serum-therapy, etc., and although intended for the laity this sentence concerning the present status of serum-therapy is well worthy of quotation here: "At the present time the experiments made have led to the discovery of one certainly curative serum—diphtheria antitoxin; a curative serum of limited application—antivenine (antidotal to serpent's venom); a certainly preventive serum—tetanus antitoxin—and a number of very doubtful serums antidotal to blood poisoning, pneumonia, and plague."

Vacancies in Temple College Medical School.—The chairs of Surgery and of Pathology and Bacteriology are vacant. Applications for these positions will be received until they are filled by the election to be held October 17th.

Smallpox Again Increases.—The diminution in smallpox reported last week proved to be only temporary, the report for the week ending October 5th showing 40 new cases and 6 deaths. During September the cases numbered 116 and thus for this year there have been 259 cases. The history of the new cases show that in most instances the patient contracted the disease from being quarantined in houses from which former smallpox patients had been removed. The clash between the authorities and parents of school children, anti-vaccinationists, etc., still continues. The Mayor has signified his willingness to cooperate with councils in removing the municipal hospital to some less densely populated section of the city.

Bequests to Charities.—The will of the late Thomas Elkinton disposes of over $100,000 to charities. The Jefferson, Orthopedic, Polyclinic, University, and Pennsylvania hospitals receive $5,000 each. On the death of the widow they each receive an additional $5,000.

Treatment of Gunshot Wounds of the Abdomen.—At the Philadelphia Academy of Surgery October 7th Drs. Le Conte and Harte each reported a case of gunshot wound of the abdomen, recovery of the patient following operation in each instance. In discussing the papers Dr. W. L. Rodman emphasized several points: (1)

the subsidence of shock should not be waited for in these cases, operation being done at once. He believes that the degree of shock in cases without hemorrhage has been greatly exaggerated, many of them having normal temperature. When present it is likely due to hemorrhage and immediate operation is then indicated; (2) pistol wounds should always be looked upon as septic; (3) drainage should practically always be used; (4) in military surgery non-intervention seems to be the better plan to pursue. In civil practice operate promptly, not waiting for symptoms.

CHICAGO.

Rush Medical College.—Fourteen graduates received diplomas September 30th from this institution at the convocation exercises held at the College. The work entitling the graduates to the degree of Doctor of Medicine had been completed during the summer quarter at the school. The address on behalf of the Faculty was given by Dr. F. C. Hotz, who selected for his subject, "What Constitutes the Practice of Medicine."

Northwestern Medical College.—The Northwestern University Medical School held its opening exercises October 1st. Despite the rigid requirements for admission, it is said that the Freshmen class is by far the largest in the history of the institution. There is also an influx of students to the higher classes, among the latter being a large delegation from the University of Iowa, where the medical department was completely wiped out by fire some months ago. Mr. James H. Eckels delivered the opening address.

Appointment of Dr. N. S. Davis, Jr.—Dr. Davis has succeeded Professor Frank S. Johnson, who resigned the Deanship of the Northwestern University Medical College. The position of Secretary, left vacant by the promotion of Dr. Davis, has been filled by Dr. A. R. Edwards.

Death of Dr. Jones.—Dr. Samuel J. Jones, Professor of Ophthalmology and Otology at the Northwestern University Medical School for twenty-five years, died at his home, Oct. 4th. He was surgeon in the eye and ear department of St. Luke's and Mercy Hospitals, and from 1887 to 1892 was Editor of the *Chicago Medical Journal and Examiner.* He was a member of the American Medical Association, and of the local medical societies. During the Civil War he was a surgeon in the United States Navy, and participated in many naval engagements. Dr. Jones was sixty-five years of age.

Illegible Prescriptions.—Public attention is called to the danger that lurks in illegible or carelessly written prescriptions by a suit for damages that has just been brought against a West Side druggist by a Chicago citizen who claims that the druggist in compounding a prescription for his baby used a compound containing 10 per cent. opium instead of 1 per cent. opium, which the prescription called for. The druggist shifts the blame to the physician who wrote the prescription, claiming that the writing was illegible. Independent of the particular allegations in this case, it is plain that the public safety is constantly menaced by careless and illegible writing of prescriptions on the part of physicians. In case of doubt, the prescription should be sent back to the physician to be deciphered.

Opening Exercises of the Chicago College of Physicians and Surgeons.—These were held in the College Building, Oct. 1st. The address to the students was delivered by Dr. Sanger Brown.

Pasteur Institute.—Chicago Pasteur Institute, in its latest report, shows that since the establishment of the institution 1,150 patients have been treated, and of this number only 7 died, making the mortality but little more than one-half of one per cent. Records of untreated cases show that the mortality is about 88 per cent. for bites on the face, 67 per cent. for bites on the hands, and 20 to 30 per cent. for bites on the limbs and body. Many States and Territories, as well as Canada, have sent patients to the Institute. Of the total number of patients received, 1,040 had been bitten by dogs. Cats had wounded 36, horses 41, skunks 12, wolves 5, cows 6, calf 2, rat one, a mule one, a pig one, and human beings 6. Of the 7 persons who died, 4 were overtaken by hydrophobia soon after reaching the Institute, many days having elapsed since they were bitten.

A Hospital for Consumptives.—A home for consumptives has been established at Austin, the corner-stone of which will be laid October 20th. The building will cost $150,000, and will occupy grounds of ten acres. It is being erected by the Sisters of St. Elizabeth's Hospital.

Bequest of Henry C. Durand.—By the will of the late Henry C. Durand, of Lake Forest, $10,000 is bequeathed to the Presbyterian Hospital.

Chicago Medical Society.—This Society held its first meeting since the summer vacation October 2nd, in its new meeting-place, Schiller Hall. Dr. N. S. Davis, Sr., delivered an interesting address on "The Origin and Progress of the Chicago Medical Society." Dr. William A. Evans presented a paper on "Fat Necrosis."

Cook County Hospital.—Dr. Arthur R. Edwards and Dr. James B. Herrick have resigned from the Executive Committee. The President, Dr. Denslow Lewis, has appointed Dr. E. Fletcher Ingals to represent Rush Medical College, and Dr. Robert B. Preble to represent the Northwestern University Medical School. The Committee elected as Chairman, Dr. Wm. E. Quine, who appointed the following subcommittees: On clinical instruction, Drs. Baldwin and Webster; records, Preble and Lewis; morgue, MacKellar and Kearsley; admission and assignments of patients, Lewis and Swan; Internes and nurses, Ingals and MacKellar; laboratory, Kearsley and Baldwin. The Chairman, *ex-officio* member of all committees.

Testimonial Banquet to Dr. S. Davis, Sr.—

Dr. N. S. Davis, Sr., was tendered a testimonial banquet October 5, 1901, at the Auditorium Hotel, Chicago. It is estimated that there were three hundred physicians in attendance from the city and elsewhere.

Dr. Frank Billings acted as Toastmaster. Dr. James H. Stowell, a member of the Committee of Arrangements, called attention to the many eminent pupils that had graduated under the instruction of the distinguished guest. He said that the Deans of three of the largest medical schools in Chicago were pupils of Dr. Davis. Dr. Frank Billings said that while Dr. Davis was a Chicagoan, he belonged to the whole country. He was a New Yorker by birth, and was born on January 9, 1817. He was looked upon as a lever to elevate medical education. Among the chief characteristics of Dr. Davis' life he mentioned industry, tenacity of purpose, progressiveness, liberality, integrity, and a Christian spirit. Dr. Edward F. Wells made a speech in which he presented a loving cup to Dr. Davis. This beautiful cup, of Grecian design, was, in its lines and proportions, a model of simple, vigorous dignity, and was selected as being peculiarly emblematic of the character and career of the distinguished guest. Engraved upon one side was an excellent likeness of Dr. Davis; upon another was the leaf of victory, and beneath it the inscription, "Palman qui meruit ferat"—let him who has won it bear the palm; and beneath this, pioneer in local and national medical organization, and in graded medical instruction, and upon the other was this memorial tribute: "Presented to Nathan Smith Davis, A.M., M.D., LL.D., in recognition of his long and distinguished services to medicine, in its every field of usefulness, by the members of that profession which he has so conspicuously adorned, and to whose shield he has given an added luster."

Dr. Davis was enthusiastically received, and, in accepting the loving cup, expressed his cordial thanks for the demonstration of kindness. He thought it would probably be the last time he would have the opportunity to address such an audience. But before he sat down, he said: "If you want to promote harmony, cordiality, advancement; if you want to build up, stop pulling down anybody. If your neighbor does not do as you think he ought to do, talk about his good qualities, and let his bad go. In this way, you will soon establish harmony, you will soon have cordiality, and will have you own heart free, and your conscience will be right before your God."

Letters and telegrams of regret were received and read from various members of the profession all over the country. The following toasts were responded to: "The American Physician," by Dr. Charles A. L. Reed, of Cincinnati, Ohio; "International Medicine," by Dr. Donald Maclean, of Detroit, Michigan; "Western Medicine," by Dr. Archibald Church, of Chicago; "Medical Education," by Dr. Victor C. Vaughan, of Ann Arbor, Michigan; "Literary Medicine," by Dr. Hobart A. Hare, of Philadelphia, Pa.; "The Physician in Public Affairs," by Dr. Robert H. Babcock, of Chicago.

A short, but appropriate, speech was made by Dr. Edwin Ricketts, of Cincinnati, Ohio. Reminiscences of Dr. Davis were related by Drs. John H. Hollister, Edmund Andrews, Norman Bridge, and Frank X. Waxham.

GENERAL.

Medical Society of City Hospital Alumni, St. Louis.—The last meeting was held Thursday, October 3d. The following papers were read: "Report of a Case of Iodoform Poisoning," by Dr. Charles H. Dixon; "Some Observations on Malarial and Blackwater Fever on West Coast of Africa," by Dr. V. P. Blair.

Registration at Harvard.—The effect of stricter admission requirements in the Medical School is shown by a falling off of about 100 in that department. Beginning this year, only graduates of recognized colleges or scientific schools will be admitted.

Huntington Mansion to Become a Hospital—The widow of Collis P. Huntington has announced that the Huntington house, at California and Taylor streets, San Francisco, will never be privately occupied again. Mrs. Huntington said: "I have determined to devote the house to some charitable purpose, just what I am not prepared to say. I may convert it into a hospital for women."

Wholesale Disinfection.—During the past summer Galveston has been disinfecting with a sprinkling cart. To the alleys, the low streets, the fronts of market houses, and the refuse of fish and oyster shops, the cart has paid almost daily visits, and it is generally admitted that the practice has done much to preserve health. The Board of Health is working on the "ounce of prevention" principle, and the disinfecting cart was part of its campaign of education in the advisability of a liberal use of disinfectants. Those who will agree to use disinfectants are furnished with them by the city without cost, and the result, according to the Galveston *News,* is that the city has been in a superior sanitary condition throughout the season.

Obituary.—Dr. R. H. Nesbitt died of gangrene of the intestine at New York Hospital, Thursday morning, Oct. 10th. Dr. Nesbitt was a resident of Wheeling, W. Va. He graduated two years ago from the College of Physicians and Surgeons with honor. In the competitive examination for New York Hospital he obtained the second appointment and has served in that hospital for the past two years. While serving in the hospital he was operated on for a severe gangrenous appendicitis and recovered. Fibrous bands which then formed are supposed to be the cause of the gangrene in the present attack. After serving his regular service in the hospital he had charge of the private pavilion and has just returned from Europe.

CORRESPONDENCE.

A MC KINLEY MEMORIAL.

A SEASIDE SANATORIUM WITH A PAVILION FOR EVERY STATE FOR THE TREATMENT OF AMERICAN CHILDREN SUFFERING FROM TUBERCULOUS AND SCROFULOUS DISEASES, OR PREDISPOSED TO CONSUMPTION.

To the Editor of the MEDICAL NEWS:

DEAR SIR: During the past week some lay and some medical journals announced that it was intended to erect in Washington a McKinley Hospital in honor of our late beloved president.

Beautiful as this idea may be, I believe that a little memorial hospital, located in Washington, is not a great enough tribute to a nation's president such as was William McKinley. Furthermore, while I would not wish to say that there is no room for a hospital for the treatment of general diseases in Washington, I know that there is no urgent need for it. On the other hand, I know, and all physicians and charity workers of our large Eastern and Western cities will bear me out when I say that there is a crying and urgent need of a sanatorium, or rather several sanatoria where the many little scrofulous and tuberculous children of poor parents could receive treatment, care and the necessary education. France, Germany, Holland, Italy, and the Scandinavian countries all have numerous seaside sanatoria where the little sufferers afflicted with the above-mentioned diseases are taken care of. The seacoast climates, combined with proper sanatorium treatment, seem to produce really wonderful results in scrofulous and tuberculous children. The reports of some of the European seaside sanatoria show an average of 75 per cent. of cures.

We in America have, with the exception of one or two small children's hospitals and a few floating hospitals during the summer months, no such institutions. In a little address delivered at the recent Congress on Tuberculosis in London, I said that in our eagerness to take care of the consumptive adult we should not forget the little sufferers afflicted with the same or other tuberculous diseases. To treat the scrofulous or tuberculous child (scrofulosis being only a milder form of tuberculosis), or to prevent a child with a hereditary tendency from developing consumption or any other form of tuberculous disease, means the saving of a life and perhaps the preservation of a very useful future citizen.

To realize the urgent need of seaside sanatoria for children one must have visited the crowded tenement districts of our great cities and seen the large number of scrofulous and tuberculous children there and the many who bear on their pale little faces the stamp of candidates for consumption (pulmonary tuberculosis).

There are already laws in some States prohibiting the tuberculous child from attending public school; but as far as I know none of these States have provided other places where children suffering, it is true, from a chronic communicable but also curable disease can receive the education to which they are entitled, much less where they could have a chance of being cured of their affliction. The results obtained in some of our American sanatoria for the treatment of tuberculous adults are as good as any of those obtained in European institutions. The preventive measures inaugurated by our New York Board of Health have not only served as models for other American cities but have been imitated by many European municipalities and found to be the most practical and efficacious. We have already a number of sanatoria for the treatment of the consumptive poor adults, though by no means enough. However, in nearly every State of the Union the question of providing institutions for adult tuberculous patients with little or no means is now being agitated. Only for the countless little ones suffering from the same or other tuberculous diseases there is nothing done.

Our good McKinley had two children, and these he lost. He dearly loved little children and the creation of a sanatorium for the treatment and prevention of a disease with which so many American children are afflicted would surely be a fitting memorial to this great man and lover of children. "McKinley Sanatorium for the Treatment and Prevention of Tuberculous Diseases in Children" should be the name of such an institution.

The meaning of the name William McKinley, written on the portals of these houses of hope for many a suffering mother's heart, will be made clear to these little inmates by their teachers and friends.

The word McKinley will embody to these little sufferers all that is needed to make them good patients, obedient pupils, noble men and women, true American citizens. McKinley's fortitude during the last days of his life must teach them what all patients need: Trust in God, confidence in their physician, patience. His words of forgiveness to the very man who slew him must show these little children the sublimity and nobleness of his character. McKinley's life as a man, citizen, patriot, and president embodies all that is truly American. A better example to teach our children the meaning of true manhood and true patriotism we can not find.

Let all American men and women who can afford it contribute through their children or through their children friends toward the realization of this McKinley sanatorium.

In letting the children of parents of means who are happy and will bring their mites toward a movement of this kind a lesson of charity and patriotism may be taught to them as well. There will be found in every community responsible and patriotic citizens to take this matter in hand and bring it to a successful issue. Let each State contribute enough to have its own pavilion in which to place its children. Let the Atlantic and Pacific coast be lined with such institutions, one or two

pavilions for each State according to its needs. Let good schools be attached to each sanatorium so that the intellectual development of the children may not suffer.

There exists in the North Sea (German Ocean), on the island called Norderney, a beautiful flourishing sanatorium for the treatment of tuberculous children. Its name is "Kaiser Friedrich Hospiz" and it was erected in memory of that unfortunate emperor Frederick the Third, whom the German people so fondly call "Frederick the Noble." In the fortitude of this beloved sovereign, in his patience, in his martyrdom, in his love for the people, in his ideas and ideals of what should constitute a free and just nation, there is a great similarity to our beloved McKinley.

We too may call our martyred ruler "the Noble," and to his memory erect a memorial of practical utility. Let us build an institution where the lives of American children can be saved; to be sent forth in health and vigor to their respective communities, and to help finish the work for which McKinley lived and died: to make the American nation the greatest, the noblest, the foremost of the world.

Very truly,
S. A. Knopf, M.D.

New York, October 9, 1901.

CHRISTIAN SCIENCE AND MENTAL EPIDEMICS.

To the Editor of the Medical News.

Dear Sir: Concerning the question of Mental Epidemics referred to in the opening of my article upon *Christian Science "Cures"* published in your issue of July 27th last, I ask you to be kind enough to print the following facts.

Epidemics of mental disease are not new, as some medical men, not alienists, of course, seem to believe. Upon the other hand, they date back as far as the year 1000. The subject is referred to at considerable length by Esquirol in his "mental maladies," of which there is an English translation. He gives a complete account of the "Miller Mania" which "Originated in the readings, reflections, and dreams of one William Miller of the State of New York, who came to know about the year 1840 at what time 'the Lord was to appear in the heavens' and the end of all things to come."

The question of mental epidemics is admirably discussed by Dr. Boris Sidis, of the New York Pathological Institute, in his most interesting book "The Psychology of Suggestion" (Appleton, 1898.) Upon page 349 of this work may be found a chronological table of "the uninterrupted chain of European epidemics."

Pilgrimage epidemic		1000 to 1095
Crusade epidemic	Eastern & Western crusades, Children's crusade.	1095 to 1270
Flagellant epidemic		1260 to 1348
Black death & antisemitic mania		1348
Dancing mania	St. John's dance	1374 to the end of the 15th century.
	St. Vitus' dance	1418
	Tarantism	1470
Demonophobia, or witchcraft mania		1488 to the end of the 17th century.
Speculative mania	Tulipomania	1634
	The Mississippi Scheme	1717
	The South Sea Bubble	1720
	And bubbles to our own times.	

I wish it distinctly understood that I have simply copied Dr. Sidis' table, and have neither added nor omitted anything.

Lawrence Irwell.

344 Hudson St., Buffalo, N. Y., Sept. 17, 1901.

WHAT CONSTITUTES A QUACK, IN THE PROPER SENSE OF THE TERM?

To the Editor of the Medical News:

Dear Sir: It occurs to the writer's mind that an expression of opinion by the Editor on the above question would be of interest and great service to News readers, stimulating them to greater efforts in studying physiological or natural methods in the treatment of disease. The fact of the News having printed an editorial some months ago on the Scientific Basis of Hydrotherapy, taking strong ground in favor of the schools devoting more time to the teaching of non-medicinal therapeutics, together with the further fact of its acceptance of a most radical article on typhoid fever by the writer, in which the greatest stress was placed on the value of hydrotherapy and therapeutic fasting, drugs being practically ignored, emboldens me to make this plea.

Let me put it in this way: Here is a physician of the most regular order, the owner of one or more parchments, practising according to our strict code of ethics and after the teachings of the schools. He loses, say fifteen out of every one hundred cases of typhoid fever, the average mortality in the Massachusetts General Hospital during the past forty years having been 15.5 per cent.

Over against this showing I will place the record of a non-graduate, or shall I say a man who twenty odd years ago "graduated" from a truck-cart; that is, he was a hard-working truckman. He got hold of a work on "The Water Cure," became greatly interested therein, and aside from that he subscribed for a health journal and read everything he could find along this line. He began practising by treating here and there one of his poor neighbors gratis. His success induced him to devote his entire time to his new work, and he finally became a very busy practitioner. For upwards of fifteen years he was one of the busiest and most successful doctors in this city. Naturally enough a great share of his practice was in cases given over by his regular contemporaries, or rather, I should say, that came into his hands

after unsatisfactory results from regular treatment.

Speaking generally, the laity demand first of all the regular stamp on their family physicians; if worse come to worst, and they have to make any change, they may consult a Christian Science faker, a spiritualistic "seer," or—a water-cure doctor! The latter may be consulted in pure ignorance of there being any special difference between empirics, as we are apt to style all irregulars. This special empiric took all sorts of cases, diphtheria, typhoid fever, pneumonia, puerperal, rheumatic, scarlet—in short every form of fever. His success was far and away beyond any regular physician in our midst. He seldom lost a patient with typhoid fever and labored energetically year after year, doing splendid work.

He was a skilled masseur; he knew how to employ water very skilfully; he never permitted a fever patient to eat a morsel of food until convalescence was fully established; he seldom employed any medicament, although he was apt to pprescribe a placebo of his own concoction, an inert water mixture that could not in the most remote way deplete the vital organism of his patient.

He was by the profession, and even by the laity in general, called a quack; but was he that? As between a doctor who goes along practising blindly and lazily after the teaching of the schools, having long illnesses and losing many patients by death, on the one hand; and, on the other, a physician such as I have described, which, let me ask, is the quack?

CHARLES E. PAGE, M.D.

Boston, Oct. 2, 1901.

A SANATORIUM FOR TUBERCULOSIS.

To the Editor of the MEDICAL NEWS:

DEAR SIR: It is a pleasure to announce that New Mexico is no longer under the reproach of not providing adequate accommodations for tuberculous invalids. An institution fully equipped for the practice of the modern therapeutics of tuberculosis has been established at Silver City, New Mexico. The Sisters of Mercy, who have it in charge, bring to bear their long experience in the management of hospitals, and sanatoria, and the fact that the Institution is conducted by them is a surety that every effort is made to maintain a high standard of efficiency.

It is a well known fact that Silver City possesses exceptional climatic advantages. The question of climate was most carefully considered in selecting a site for the U. S. General Hospital for the treatment of tuberculous soldiers, and the representatives of the Government finally decided upon Fort Bayard, six miles from Silver City.

Writing particularly of Silver City, Prof. C. B. Penrose of the University of Pennsylvania states that he spent two years roaming over this arid district and that as a result of his personal experience he believes that a greater proportion of cases get well in New Mexico than in any other Territory or State. (Wood's Practice.)

The maximum amount of rainfall is less than 15 inches. The complete aridity of the region attests the dryness of the atmosphere. Both heat and cold are unknown. Our summers are cool and winters warm, the former condition being the result of an altitude of 6,000 feet—itself a manifest advantage, and the latter due to the latitude, which is that of Savannah, Ga. Then, comfortable outdoor life is practicable at all times during the year. In this respect we are more fortunate than other southwestern resorts where the weather is enervatingly warm during the summer. The last annual report of the U. S. General Hospital at Fort Bayard conclusively demonstrates the utility of our climate in the treatment of pulmonary and laryngeal tuberculosis.

The régime at St. Joseph's Hospital includes careful medical supervision, as well as very possible sanitarium comforts. The cuisine is first-class, rooms airy and cheerful and porches commodious. Complete reports of progress in any case are furnished the home physician when desired.

Very respectfully,
E. S. BULLOCK, M.D.,
Medical Director.

Silver City, N. M., September 28, 1901.

THE PROGNOSIS OF ASCENDING GONORRHEA IN WOMAN — RESPIRATION DURING THORACIC ANKYLOSIS—TRAUMATIC TABES—MYELOGENOUS BONE-TUMORS—GASTRIC CARCINOMA.

THORN, at the Medicinische Gesellschaft zu Magdeburg, June 6, 1901, read a paper on the subject of ascending gonorrhea in the female and more especially on its immediate and ultimate prognosis. There is at the present time a mild reaction in Germany against the former immediate and more or less radical operative interference in this case, which implied unilateral or bilateral extirpation of the adnexa. A conservative, often non-operative therapeusis, is now the rule and in his own opinion has been for many years the proper one. Recently Krönig published a series of valuable statistics on this subject which bear out this opinion and render discussion of the subject proper. If one can positively show that the primary and secondary prognosis of this ascending disease is far better than it was formerly pronounced to be; then the number of "clearings out of the pelvis" and other visceral ablations will decrease and the therapeusis of the trouble assume a kindlier and less damaging phase, especially in the large cities. How difficult this will be in the face of a false prudery is at once apparent, even among such a class of people as the maritime. Thorn has,

however, had the good fortune to see a large number of relatively early cases of gonorrhea in women, the ascension of which was successfully hindered by the timely and proper application of suitable remedies. Extension upward of any bacteria is normally and effectually hindered by the anatomical conditions at the internal os uteri. This rampart is usually scaled only during menstruation or the early puerperium or by the improper use of sounds, irrigations, applications and curetting. Suitable means, however, aside from these conditions which favor promulgation of the cocci, do succeed although the so-called abortive treatment usually leaves little result behind. The use of the sound must be limited more and more in gynecology and always with increasing aseptic and antiseptic precautions. Probably the instrument can be practically discarded altogether in the presence of other carefully combined examinations. Whenever possible the patient must be put to bed and in charge of a nurse, with full warning to and understanding by both of the great responsibility inherent in any relaxation of the treatment and especially in any exposure to reinfection. If the gonococcus has really invaded the corporal endometrium it may still be possible to avoid its entrance into the tubes if only a precocious local treatment is carefully avoided. An active gonorrheal endometritis permits no local interference with safety, but the usual post-gonorrheal inflammations are the very ones which do. Even after the tubes and parametrium have become involved, complete restitution, with preservation of the powers of conception, is possible. The early peri-uterine reaction may easily deceive the inexperienced into believing the changes to be permanent. The rapid enlargement of the tube, the various adhesions present often recede or disappear entirely under appropriate antiphlogistic treatment and rest in bed. The rapidly developed and often astonishing tumors which appear in the pelvis are made up not so much of the tubes with intratubal exudates as of the tubes with their contents augmented by peritubal exudates, adhesions, seroceles and intestinal coils. It may seem parodoxical, but yet it appears to be a fact, more and more, that the invasion of the peritoneum by the gonococcus is rarely if ever fatal. To this statement the recent researches of Bumm lend authority and, therefore, too premature a laparotomy must be avoided. Bumm has stated that the gonococcus practically never causes death by peritonitis in woman. Wertheim has shown that this germ can not penetrate the myometrium. Hence it must be concluded that when a parametritis occurs, probably a mixed infection was present at the outset. Admittedly only a few of the advanced cases of ascending gonorrhea result in absolute restitution, but of the others during the course of the first year a recession of all the complications commonly results from good treatment and from that period onward, the tendency is toward a more or less complete restitution of the visceral functions. According to the admirable statistics of Bumm and Krönig, in about 90 per cent. of all cases such an improvement takes place during the first five years. The question of sterility is also, according to these observers, not so serious a one as many authors have in the past claimed. The older and especially the newer results all tend to show that the prognosis of ascending gonorrhea is not as serious as was at first suspected and when one considers the unpromising records of the early operative therapeusis this fact is more and more established. In perhaps fifty to sixty per cent. early operation has failed to produce any very great success. The total ablation of the internal organs of generation would probably be better, but except in women near their menopause no one would recommend this. It is in the young women sexually that these troubles are usually encountered and to such a premature menopause is often disastrous. Even in the operative cases vaginal incision and drainage of these pus-collections require better judgment and skill than does the laparotomy. It is certain, therefore, that in the future the treatment of choice for these cases will be first the expectant, then the operative of which the total ablation of the adnexa is a last resort.

J. Müller, at the Physikalisch-medicinische Gesellschaft zu Würzburg, July 18, 1901, noted his observation of a case of progressive inflammatory ankylosis of the thoracic vertebral column, continuing to involve the rib-joints also. Therefore, the changes in the volume of the chest which follow upon the rise and fall of the ribs are absent and breathing is confined solely to the action of the abdominal muscles and the diaphragm. The rest of the symptom-complex, which Strümpel was the first to fully describe, was by this case entirely ratified. Only the lowermost ribs were movable at all and then only to the limit of 6.5 cm. in circumference. The rest of the ribs moved only a very little, even in deep respiration. The excursions of the abdominal muscles, however, were very much augmented, so that at the navel they reached the limit of 4.5 cm. Expiration was marked by the appearance of a deep abdominal furrow. The vital capacity of the chest was decreased by nearly 400 c.cm. under the normal standard of 2040 c.cm. One might assume then that compensatory abdominal respiration may produce various secondary effects. Dyspnea was present in a short time following any effort at forced respiration, not in its frequency as in its depth. The natural number of respirations was 22 to 24 in bed to 20 to 22 on the feet. The pulse was regularly accelerated to about 100 and upon easy effort to about 140. This may have been due to the impediment offered the heart by the overacting diaphragm. The typical bending of the trunk forward seems to be due to the abnormal play of the abdominal muscles and was present in this patient to a marked degree.

Strauss, at the Gesellschaft der Charité-Aerzte in Berlin, July 18, 1901, gave a clinical

demonstration of traumatic tabes. The workman had fallen into a ditch two years before the development of left-sided ataxia, emaciation, absence of pupillary reflexes and of the patellar reaction. After the accident only a difference in the pupils was noted. Infection and inflammation from cold were both denied.

Von Kryger, at the Aertzlicher Bezirksverein zu Erlangen, June 24, 1901, read a paper discussing conservative treatment in surgery of myelogenous bone-tumors. The burden of his conclusions rested upon several cases and their results, of which the following are the most important. From the lower third of the humerus of a man a sarcoma was taken in such a manner that only a small shell of bone carrying the internal condyle remained. The patient made a perfect recovery, but has a movable joint. In a young girl a sarcoma was also taken from the femur, involving much of the internal tuberosity. About sixteen centimeters of its lower extremity were sacrificed and the bone-stump morticed into a socket chiseled out in the head of the tibia. The result in this patient is not yet complete, but promises well for the immediate present. At this moment she is going about with a plaster-of-Paris dressing. Such results, of course, have no reference to the question of ultimate recurrence of the growth and certainly are not comparable to such as usually follow high amputation in this respect, but they are less dreadful for the patient to contemplate and usually secure a much earlier permission to operate. Moreover, function with part of a normal limb, as in both of the above cases, is easier and better than with the most finely adjusted apparatus. A comparison can in broad terms be made to the conservative treatment of carcinoma of the stomach. We see, for example, in cases of gastric carcinoma. The most severe symptoms of obstruction disappear after the operation, the patient gains greatly in weight and strength and lives happily for a year or more, although the tumor goes quietly on growing. Similarly cicatricial stenoses of the pylorus may be greatly benefited by the more conservative treatment. At Erlangen Von Hacker's retrocolic method is preferred to Wölfler's antecolic method. The after-treatment in these gastric cases is important. As a rule rectal feeding should be employed at first. Then fluids by mouth and finally after two weeks, sometimes less, full diet. As a rule, all cases do very well under this regimen.

THERAPEUTIC HINTS.

Cuprol and the Eye.—S. Snell (*Lancet*, Sept 14, 1901) states that cuprol, the new combination of six per cent. copper with nucleinic acid, is a most valuable substitute for copper sulphate in the various conjunctival affections in the eye. Less irritating, more penetrating, not coagulating with albumin and alkalis, less painful in actual application, and, so far as results at present have shown, equally active therapeutically as the old "blue stone," it seems to be in virtue of these characteristics a most desirable substitute for it. He has used it with great satisfaction in granular lids, trachoma and pannus and purposes extending it field of application to the other conjunctival affections.

Treatment of Psoriasis.—At a meeting of the Dermatological Society of Vienna, H. Steiner (*Revue de thérap.*, Sept. 1, 1901) presented a patient, thirty-eight years old, who had been suffering with psoriasis for nine years. He had been treated in different hospitals with tar, pyrogallic acid, arsenic, with but little success. He had constant relapses. Four weeks prior to his presentation to the society he came to the author with an acute attack. He was given a hypodermic injection of half a syringeful of boiled Levico water, in the dorsal region. On the third day a syringeful was injected; on the fifth day, 2 syringefuls; on the tenth day, 3 syringefuls, etc. In all, the patient received 22 injections. There was continuous amelioration and at the time of presentation the previous diseased skin presented only slight pigmentation. The injections of Levico water are easily made, act rapidly and gastric disturbance is avoided. In therapeutic action, Levico water is very much like the cacodylates. It is claimed that sulphur which it contains in combination is an advantage, as it is said to exert a vaso-constrictor influence.

BOOK REVIEWS.

A Text-book of Gynecology. Edited by Charles A. L. Reed, A.M., M.D., Gynecologist and Clinical Lecturer on Surgical Diseases in Women at the Cincinnati Hospital; Fellow of the American Association of Obstetricians and Gynecologists; Fellow of the British Gynecological Society, etc. D. Appleton & Co., New York.

This is the latest development in the evolution of the composite book and is peculiar to itself. In its original form the composite work was simply a conglomerate, the various chapters being written by different men and standing as they were written, the editor doing little more than writing an introduction and serving as a whip to secure the material from the various authors. In the next stage the editor felt the necessity of eliminating repetitions and harmonizing the material so as to give the volume more homogeneity. Practically the editor rewrote everything and eliminated the individuality of the various authors. This reached its extreme limit noticeably in the American Text-Book of Gynecology. In the volume under consideration the editor has

remodeled the material of every contributor to a greater or less extent and tells in narrative form what the original writer had to say upon the subject. Thus, Dr. Foster is credited with the paragraph on nomenclature and we quote: "The language of medicine, says Dr. Frank P. Foster, is by no means free from the defective neologisms that are to be found in the contemporary literature of the other sciences. * * * He considers that their formation is for the most part to be attributed to the rage for designating diseases, operations, and the like, by single words." To take another illustration. Dr. Carstens is credited with the paragraphs on Palliative Treatment of Cancer and we find these sentences: "Carstens has observed cases in which this treatment has been followed by perfect healing, etc. * * * In such cases Carstens proceeds as follows: * * * Carstens applies it at once as follows," and so on. This method necessitates the constant repetition of the author's name and gives to each chapter the character of an editorial comment on the author's article. This is not necessarily objectionable, but we call attention to it as the latest method of text-book making.

The work is a composite from thirty-one different specialists, all Americans except the four who were drawn from Great Britain. These are not all gynecologists. It was considered best that the various departments of medical science synthetically related to gynecology should be represented by their respective specialists, pathology by a pathologist, bacteriology by a bacteriologist, dermatology by a dermatologist, etc. Consequently a single chapter may be the product of the contributions of several writers each one contributing a paragraph or more upon that part of the subject following in his department. The effort of the editor has been to render this all consecutive, systematic and homogeneous in the manner just described.

In the list of contributors appear the names of Ballantyne of Edinburgh, Murdock Cameron of Glasgow, Sinclair of Manchester, England, Coe, Dercum, Hare, Herzog, Mann, Dan Millikin, Warren Potter, Newman, Rothrock, Tabor Johnson, and others to the number, as we have said, of thirty-one. The result is on the whole a very satisfactory work. It presents in a vigorous, fresh and attractive way the present status of gynecology in all its multifarious details. It should be called a treatise on gynecology rather than a text-book, for in no way is it adapted to the student's use unless it be the post-graduate student. The ideal text-book in this specialty is yet to appear and when it does come it must be the work of one who has the faculty of omitting the doubtful, uncertain, and non-essential features, simplifying the abstruse and elaborate, and setting forth the essentials in strong and graphic light.

The book before us does honor to American gynecology. It is a valuable treatise, forceful, complete, interesting, instructive and well-illustrated. It is the latest and the best.

ANATOMIE GÉNÉRALE APPLIQUÉE A LA PHYSIOLOGIE ET A LA MÉDECINE. Par XAVIER BICHAT. Premiere Partie. Premier Fascicle. G. Steinheil, Paris.

THE author here presents a volume which he believes to be an exposition of a new point of view. The plan is to consider in detail each of the simple systems which by their combinations form our various organs, and in this substratum build up a medical system based on the individual characters of these distinctive tissues.

How well this has been done must be determined when the entire work has been given us, but from a hasty reading it would seem that the work abounded in fanciful and theoretical allusions somewhat comparable to "newspaper science" of the yellow type.

A MANUAL OF SURGICAL TREATMENT. By W. WATSON CHEYNE, M.B., F.R.C.S., Professor of Surgery in King's College, London, and F. F. BURGHARD, M.D., F.R.C.S., Surgeon to King's College Hospital, London. Volume V. The Treatment of the Surgical Affections of the Head, Face, Jaws, Lips, Larynx and Trachea; and the Intrinsic Diseases of the Nose, Ear and Larynx by H. LAMBERT LACK, M.D., F.R.C.S., Surgeon to the Hospital for Diseases of the Throat, London. Lea Brothers & Co., Philadelphia and New York.

As in the former volumes of this series, the foremost place is given to treatment of the surgical affections discussed, while diagnosis and pathology are relegated to the background. As we have previously pointed out, the volumes will, when they are completed, form a manual of surgical therapeutics which covers the entire field of surgical pathology. The present volume is no exception to its predecessors in thoroughness, in literary style, and in the description of perfect surgical technic. As has previously been the case, the authors have well described the after-treatment of surgical operations, details which are usually lacking in mere surgical text-books.

We note with pleasure that the authors do not approve of craniectomy for microcephalus, an instance which discloses clearly, we think, how they have caught the spirit of advanced modern surgery. The various plastic operations are well described, while the description of the surgical measures dealing with the special organs of respiration is exceedingly thorough and readable. The volume is profusely and well illustrated.

PATHOLOGIE GÉNÉRALE ET EXPÉRIMENTALE. LES PROCESSUS GÉNÉRAUX. I. Histoire naturelle de la maladie—Heredite—Atrophies—Degenerescence—Concretions—Gangrene. Par MM. A CHANTEMESSE, Professeur de Pathologie Experimentale, Paris, et W. W. PODWSSOTSKY, Professeur de Pathologie générale, Odessa. C. Naud, Paris.

THIS in the first contribution of 428 pages to a history of the aims and purposes of general and

experimental pathology. It is devoted to a study of those common factors which underlie abnormal function and does not attempt to enter the domain of special pathology by considering the details of the changes in any particular organ.

In introducing the general subject of sickness, the authors immediately go to the fundamental tissues and present us with a complete dissertation on cytology which leads up to the interesting topic of cellular heredity and to pathological heredity. The most recent observations of the biologist are here to be found and the discussion is well worth the reading.

Cellular nutrition is then taken up and the various atropic troubles leading to degeneration considered. This is an extremely interesting chapter, both from the standpoint of good science and for the suggestibility of the ideas set forth.

Following this the different types of degeneration, parenchymatous, hyaline, amyloid, corneus, watery, mucous, colloidal, glycogenic, fatty, pigmentary, etc., are treated in full, and illustrated with a beauty and fulness rarely seen.

Deposits, incrustations and concretions are taken up in Chapter VIII., and in Chapter IX., the concluding chapter, necrosis, mortification and gangrene are considered.

From all points of view this is a desirable addition to the works on general pathology, giving as it does the latest and best information on the subjects treated in a comprehensive and authoratative and excellent manner. The publishers have given a beautiful volume and are to be congratulated on the high character of their work.

SYPHILIS; ITS DIAGNOSIS AND TREATMENT. By WILLIAM S. GOTTHEIL, M.D., Professor of Dermatology and Syphilology, New York School of Clinical Medicine; Dermatologist to the Lebanon and Beth-Israel Hospitals, the West-Side German Dispensary, etc. G. P. Engelhard & Company, Chicago.

THIS little book is, as the author states in his preface, intended especially for the general practitioner "who treats syphilis only occasionally or incidentally." But as the subject is carefully and concisely, though, of course, most superficially described, and the advice given invariably sound and commendable, we see no reason why this little work should not find a field of usefulness beyond that mentioned by its author. There are quite a number of well-chosen and most useful illustrations, and in paper, print and binding, the publishers have left little to be desired. For a clear and attractive introduction to the study of syphilis, Dr. Gottheil's small manual may be thoroughly recommended.

BOOKS RECEIVED.

The MEDICAL NEWS *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* MEDICAL NEWS *will shortly appear.*

TRAITÉ DE MÉDECINE ET DE THÉRAPEUTIQUE. By Drs. P. Brouardel and A. Gilbert. Tome 8. Maladies des Pleures et du Mediastin. Maladies de l'Axe Cerebro-Spinal. Par MM. Landouzy, M. Labbé, Galliard, Menetrier, Boinet, Achard, Ballet, P. Marie, Levi and Klippel. 8vo, 848 pages. Illustrated. J. B. Bailliere et Fils, Paris.

THE DISEASES OF THE RESPIRATORY ORGANS, ACUTE AND CHRONIC. By Dr. W. F. Waugh, 12mo, 221 pages. Illustrated. G. P. Engelhard & Co., Chicago.

INTERNATIONAL CLINICS. Vol II., Eleventh Series, 1901. J. B. Lippincott Company, Philadelphia.

SEXUAL HYGIENE. 12mo, 269 pages. The Clinic Publishing Company, Chicago.

SPECIAL ARTICLES.

THE CASE OF PRESIDENT M'KINLEY.

THE following report has received the approval of, and is issued by, the undersigned, the medical staff attending the late President, William McKinley.

P. M. RIXEY.
MATTHEW D. MANN.
HERMAN MYNTER.
ROSWELL PARK.
EUGENE WASDIN.
CHARLES MCBURNEY.
CHARLES G. STOCKTON.

October 12, 1901.

SURGICAL HISTORY.

President William McKinley was shot, by Leon F. Czolgosz, in the Temple of Music, at the Pan-American Exposition, Buffalo, N. Y., at about 7 minutes past 4 on the afternoon of Friday, September 6, 1901. Two shots were fired. One bullet struck near the upper part of the sternum, and the other in the left hypochondriac region. The President was immediately conveyed to the Emergency Hospital on the Exposition grounds by the motor ambulance, where he arrived at 4.18. Dr. G. McK. Hall and Mr. Edward C. Mann, medical student, of the house staff, were in charge of the ambulance, Medical Student T. F. Ellis being the driver.

On arriving at the hospital, President McKinley was at once placed upon the table in the operating room and undressed. During the removal of his clothing a bullet fell out and was picked up by Mr. Ellis. Dr. Hall placed a temporary antiseptic dressing over the wounds, and Mr. Mann ordered a nurse to administer 0.01 gm. of morphin and 0.002 gm. of strychnin hypodermically.

Dr. Herman Mynter, who had been telephoned from police headquarters to report immediately at the Exposition hospital, was the first surgeon to arrive, at 4.45 o'clock. At that time Drs. P. W. Van Peyma and Joseph Fowler, of Buffalo, and Dr. Edward Wallace Lee, of St. Louis, were present. Dr. Mynter brought with him Dr. Eugene Wasdin, of the United States Marine-Hospital Service.

Dr. Mynter inspected the President's wounds, and immediately saw their serious nature. He told the President that it would be necessary to operate, and at once set about making preparations, aided by the house staff and nurses and Dr. Nelson W. Wilson, Sanitary Officer of the Exposition, who at that time assumed charge of the hospital in the absence of Dr. Roswell Park, the Medical Director of the Exposition. The President's pulse on the arrival of Dr. Mynter was 84; he had no particular pain in the abdomen, and no apparent loss of liver dulness. He was evidently slightly under the influence of the morphin.

Dr. Matthew D. Mann arrived at the hospital at 5.10 p. m., having been telephoned for by Mr. John C. Milburn. He was followed, 5 minutes later, by Dr. John Parmenter.

An examination was at once made, followed by a short consultation between Drs. Mann, Mynter and Wasdin, which resulted in the decision to operate at once. The necessity for the operation was explained to President McKinley, and he gave his full consent. Immediate operation was decided upon because of the danger of possible continued internal hemorrhage and of the escape of gastric or intestinal contents into the peritoneal cavity, and because the President's pulse was getting weaker. Moreover, the daylight was rapidly failing. Dr. Roswell Park, who, by virtue of his office, had he been present would have performed the operation, was at Niagara Falls, and although a special train had been sent for him, it was uncertain when he would arrive.

Dr. Mann was selected to do the operation, with Dr. Mynter as his associate, by the common consent of the physicians present and at the request of Mr. Milburn, president of the Pan-American Exposition, who stated that he had been requested by President McKinley to select his medical attendants. Dr. Mann selected Drs. Lee and Parmenter as assistants.

At 5.20 Dr. Mann directed the administration of ether to President McKinley, and requested Dr. Wasdin to administer it. Ether was chosen as being, on the whole, the safer anesthetic. While the anesthetic was being given the surgeons who were to take part in the operation prepared their hands and arms by thoroughly scrubbing with soap and water and immersing them in a solution of mercuric chlorid.

The operation began at 5.29. Dr. Mann stood upon the right-hand side of the patient, with Dr. Parmenter on his right-hand side. Dr. Mynter stood upon the left-hand side of the patient, and on his right was Dr. Lee. To Drs. Parmenter and Lee were assigned the duties of sponging and the care of the instruments. Dr. P. M. Rixey, U. S. N., President McKinley's family physician, having been detailed by the President to accompany Mrs. McKinley to the Milburn home, did not arrive until 5.30, when he gave very efficient service by guiding the rays of the sun to the seat of the operation by aid of a hand-mirror, and later by arranging an electric light. Dr. Roswell Park arrived just as the operation on the stomach was completed, and gave his aid as consultant. Mr. E. C. Mann had charge of the needles, sutures and ligatures. Mr. Simpson, medical student, was at the instrument tray.

The nurses, under the charge of Miss A. C. Walters, superintendent of the hospital, were Miss M. E. Morris and Miss A. D. Barnes, with hands sterilized; Miss Rose Baron, Miss M. A. Shannon and Miss L. C. Dorchester, assistants, and Miss Katharine Simmons attending the anesthetizer.

Besides those immediately engaged in the operation, there were present Drs. P. W. Van Peyma, Joseph Fowler, D. W. Harrington and Charles G. Stockton, of Buffalo, and Dr. W. D. Storer, of Chicago.

THE OPERATION.

President McKinley took the ether well, and was entirely under its influence in 9 minutes after the beginning of the anesthetization. The abdomen was carefully shaved and scrubbed with green soap, and then washed with alcohol and ether and the bichlorid solution.

Inspection showed 2 wounds made by the bullets. The upper one was between the second and third ribs, a little to the right of the sternum. The use of a probe showed that the skin had not been penetrated, but that the bullet had probably struck a button or some object in the clothing which had deflected it. The lower wound made by the other bullet—a 32 caliber—was on a line drawn from the nipple to the umbilicus. It was about half-way between these points, and about 5 cm. to the left of the median line. A probe showed that this wound extended deeply into the abdominal walls, and that the direction was somewhat downward and outward.

An incision was made from the edge of the ribs downward, passing through the bullet wound and nearly parallel with the long axis of the body. A deep layer of fat was opened, and followed by incision of the fascia and muscles to the peritoneum. After cutting through the skin, a piece of cloth, undoubtedly a bit of the

President's clothing, was removed from the track of the bullet, a short distance below the skin.

On opening the peritoneum, the finger was introduced and the anterior wall of the stomach palpated. An opening was discovered which would not quite admit the index finger. This opening was located near the greater curvature of the stomach, and about 2 cm. from the attachment of the omentum; its edges were clean-cut and did not appear to be much injured.

The stomach was drawn up into the operation wound, and the perforation very slightly enlarged. The finger was then introduced and the contents of the stomach palpated. This was done to see if the stomach contained food, and also with the hope that possibly the bullet might be in the stomach. The stomach was found to be half-full of liquid food, but no evidence of the ball was discovered. In pulling up the stomach a small amount of liquid contents escaped, together with a good deal of gas. The tissues around the wound were carefully irrigated with hot salt solution and dried with gauze pads. The perforation in the anterior stomach wall was then closed with a double row of silk suture (Czerny-Lembert). The sutures were not interrupted with each stitch, but 4 stitches were introduced before the ends were tied. The loop was then cut off and the suture continued. About 8 stitches were used in each row. The silk used was fine black silk, the needle being a straight, round sewing needle.

In order to examine the posterior wall of the stomach, it was necessary to enlarge the incision, which now reached about 15 cm. in length. The omentum and transverse colon were pulled well out of the abdomen. The omentum was enormously thickened with fat and very rigid. In order to reach the back wall of the stomach, it was necessary to divide about 4 inches of the gastrocolic omentum, the cut ends being tied with strong black silk in 2 masses on each side. In this way the stomach could be drawn up in the operation wound, and the bullet wound in its posterior wall reached. This opening was somewhat larger than that in the anterior wall of the stomach, and had frayed and blood-infiltrated edges. Its exact location was impossible to determine, but it appeared to be near the larger curvature.

This opening was closed in the same way as the anterior wound, but with great difficulty, as the opening was down at the bottom of a deep pocket. A short curved surgical needle was necessary here. Little or no gastric contents appeared around this opening, but after it had been closed the parts were carefully irrigated with hot salt soltuion.

The operation on the stomach being now finished, Dr. Mann introduced his arm so as to palpate carefully all the deep structures behind the stomach. No trace of the bullet or of the further track of the bullet could be found. As the introduction of the hand in this way seemed to have a bad influence on the President's pulse, prolonged search for further injury done by the bullet or for the bullet itself was desisted from. The folds of the intestine which had been below the stomach were inspected for injury, but none was found. The entire gut was not removed from the abdomen for inspection, as the location of the wound seemed to exclude its injury. To have made a satisfactory search for wounds in the President's back, it would have been necessary to have entirely eviscerated him. As he was already suffering from shock, this was not considered justifiable, and might have caused his death on the operating table.

Before closing the abdominal wound, Dr. Mann asked each of the surgeons present, whether he was entirely satisfied that everything had been done which should be done, and whether he had any further suggestions to make. Each replied that he was satisfied. The question of drainage was also discussed. Dr. Mynter was in favor of a Mikulicz drain being placed down behind the stomach-wall. Dr. Mann, with the concurrence of the other surgeons, decided against this, as being unnecessary.

As the last step in the operation, the tissues around the bullet track in the abdominal wall were trimmed, in order to remove any tissue which might be infected. The abdominal wound was then closed with 7 through-and-through silkwormgut sutures, drawn only moderately tight, the superior layer of the fascia of the rectus muscle being joined with buried catgut. The edges of the skin were brought together by fine catgut sutures. Where the bullet had entered there was slight gaping of the tissues, but it was not thought advisable to close this tightly, as it might allow of some drainage. The wound was then washed with hydrogen dioxid and covered with aristol powder and dressed with sterilized gauze and cotton, which were held in place with adhesive straps. Over all was put an abdominal bandage.

The President bore the operation very well. The time from the beginning of the administration of the anesthetic until its discontinuance was exactly an hour and 31 minutes; the operation was completed at 6.50 p. m., having lasted from the time of the first incision, an hour and 21 minutes. At the beginning of the operation President McKinley's pulse was 84. At 5.38, 0.002 gm. of strychnin was administered hypodermically. At 5.55 the respiration was 32 and the pulse 84—both good in character. At 6.09 the pulse was 88. At 6.20 it was 102, fair in character; respiration 39. At 6.22, 1.50 gm. of brandy was administered hypodermically. At 6.48 the pulse was 124, the tension good but quick; respiration 36. At 7.01, after the bandage was applied, the pulse was 122 and the respiration 32. At 7.17, 0.004 gm. of morphin was administered hypodermically.

At 7.32 the patient was removed from the hospital in the ambulance. Dr. Rixey asked Drs. Park and Wasdin to go in the ambulance, as his duty called him to go at once to inform Mrs. McKinley of her husband's condition and to prepare a room for his reception. Drs. Mann and Mynter, with friends of the President, followed in carriages immediately after. President McKinley had not then recovered from the anesthetic. He bore the journey to Mr. Milburn's house exceedingly well, but it was found necessary to give him a small hypodermic injection of morphin during the transit, as he was becoming very restless. On arrival at the house of Mr. Milburn, 1168 Delaware Avenue, he was removed from the ambulance on the stretcher, and carried to a room in the northwest corner of the house, where a hospital bed had been prepared for him.

REMARKS ON THE OPERATION.

BY MATTHEW D. MANN. M.D.

The difficulties of the operation were very great, owing partly to the want of retractors and to the failing light. The setting sun shone directly into the room, but not into the wound. The windows were low and covered with awnings. After Dr. Rixey aided us with a hand mirror, the light was better. Toward the end of the time a movable electric light with reflector was put in use. The greatest difficulty was the great size of President McKinley's abdomen and the amount of fat present. This necessitated working at the bottom of a deep hole, especially when suturing the posterior wall of the stomach.

The operation was rendered possible and greatly facilitated by a good operating table and the other appliances of a hospital, and by the presence of many trained nurses and assistants. Still, the hospital was only equipped for minor emergency work, and had but a moderate supply of instruments. Unfortunately, when called I was not told what I was wanted for, and went to the Exposition grounds entirely unprepared. Dr. Mynter had his large pocket case, the contents of which were of great use.

As has already been noted, further search for the bullet was rendered inadvisable by the President's condition. The autopsy shows that it could not have been found, and that the injuries inflicted by the bullet after it passed through the stomach, were of such a nature as to render impossible and unnecessary any further surgical procedure. A bullet after it ceases to move does little harm. We were often asked why, after the operation, we did not use the x-ray to find the bullet. There were several reasons for this. In the first place, there were, at no time any signs that the bullet was doing harm. To have used the x-ray simply to have satisfied

our curiosity would not have been warrantable, as it would have greatly disturbed and annoyed the patient, and would have subjected him also to a certain risk. Had there been signs of abscess-formation, then the rays could and would have been used.

My reason for not draining was that there was nothing to drain. There had been no bleeding nor oozing; there was nothing to make any discharge or secretion; the parts were presumably free from infection, and were carefully washed with salt solution. As there was no peritonitis and the abdomen was found post mortem to be sterile, we may safely conclude that no drainage could have been provided which would have accomplished anything. My experience teaches me never to drain unless there is a very decided indication for it, as a drain may do harm as well as good.

In conclusion, I wish to thank all the gentlemen who so kindly and skilfully assisted me. They were all surgeons of large experience in abdominal surgery, and their aid and advice were most valuable. Especially I wish to acknowledge my great obligation to my associate, Dr. Mynter. Not only was he an assistant, but he was much more, and helped me greatly by his skill and, as a consultant, with his good judgment and extensive knowledge of abdominal work. Although called first, he waived his claim, and generously placed the case in my hands, willingly assuming his share of the responsibility.

The anesthetic was most carefully administered by Dr. Wasdin, and the knowledge that he had charge of this very important duty relieved me of any anxiety on that score.

In the eventful week that followed the operation, Dr. Park and Dr. McBurney were towers of strength in helping to decide the many difficult questions which came up.

Dr. Rixey was in constant charge of the sick-room, aided later by Dr. Wasdin, who was detailed for this special duty. Both were unremitting in their care, and faithful to the end.

Dr. Stockton helped us in the last 3 days with the highest skill and best judgment.

Never, I am sure, under like circumstances, was there a more harmonious or better-agreed band of consultants. That our best endeavors failed was, I believe, no fault of ours; but it must be an ever-living and keen regret to each one of us, that we were not allowed the privilege of saving so noble a man, so attractive a patient, and so useful a life.

THE AFTER-TREATMENT.

When put to bed the President was in fair condition: Pulse, 127; temperature, 100.6°; respiration, 30. The nurses on duty were Miss K. R. Simmons and Miss A. D. Barnes, from the Emergency Hospital. Soon after his arrival, at 8.25, he was given morphin, 0.016 gm., hypodermically. There was slight nausea. The pulse soon improved. During the evening the patient slept at intervals, vomiting occasionally, but rallied satisfactorily. A slight discoloration of the dressings was noted at 10.45. There was occasional and slight pain. Ninety cc. of urine was voided, and an enema of salt solution given and retained.

SECOND DAY, SATURDAY, SEPTEMBER 7.

After midnight the patient slept a good deal; he was free from pain and quite comfortable.

At 6 a. m., the temperature was 102°; pulse, 110; respiration, 24.

Gas in large quantities was expelled from the bowels. A saline enema was given as before. Miss Simmons and Miss Barnes were replaced by Miss Maud Mohan and Miss Jane Connolly. Miss E. Hunt, of San Francisco, Cal., Mrs. McKinley's nurse, also rendered assistance, and Miss Grace Mackenzie, of Baltimore, Md., arrived September 9, and was detailed for regular duty. P. A. Eliot, J. Hodgins and Ernest Vollmeyer, of the U. S. A. Hospital Corps, were detailed as orderlies.

During the forenoon, 0.01 gm. of morphin was administered hypodermically.

At 1.15 p. m., a saline enema of 500 cc. was given. As the pulse was rising, 0.06 gm. of fluid extract of digitalis was injected hypodermically.

The President rested quietly until 6.30 p. m., when he complained of intense pain in the pit of the stomach, and was given 0.008 gm. of morphin sulphate hypodermically. He was very restless, but after being sponged rested again.

At 6.30 p. m., the pulse was 130; temperature, 102.5°; respiration, 29.

During the day the digitalis, morphin and saline enemas were kept up at regular intervals; 4 gm. of somatose was added to the water at 10.30 p. m. At 11.15 p. m. the President passed from the bowels 240 cc. of a greenish colored fluid and some particles of fecal matter.

The total amount of urine for 24 hours was 270 cc.

FIRST URINALYSIS, BY DR. H. G. MATZINGER.

Quantity	30 cc.
Color	dark amber
Reaction	strongly acid
Urea	0.028 gm. per 1 cc. of urine
Albumin	a trace
Phosphates and chlorids	normal
Sugar	none
Indican	very small amount

Microscopical Examination.—The sediment obtained by centrifuge shows a large amount of large and small epithelial cells with some leukocytes and occasional red cells. There is a comparatively large number of hyaline casts, principally small, with some finely granular ones; also an occasional fibrinous one. The amount of sediment is large for the quantity of urine submitted. There were no crystals in the sediment.

THIRD DAY, SUNDAY, SEPTEMBER 8.

During the early morning the President slept a good deal, but was restless, and at times confused and a little chilly. On the whole, he passed a fairly good night.

He expelled a little gas and brown fluid from the rectum. The digitalis was continued, and at 7.45 a. m., 0.002 gm. of strychnin were given hypodermically. At 8.20 a. m. he was clear and bright, with the pulse strong and of good character.

The wound was dressed at 8.30, and found in a very satisfactory condition. There was no indication of peritonitis. Pulse, 132; temperature, 102.8°; respiration, 24.

The dressing on the wound was changed because there was some exudation. The bullet track was syringed out with hydrogen dioxid. There was very little foaming, and there were no signs of pus.

At 10.40 a. m., following an enema of Epsom salts, glycerin and water, he had a small stool with gas, and another at noon. He was less restless and slept a good deal.

At noon Dr. Charles McBurney joined the medical staff in consultation.

Bulletin 14, 12 m.—The improvement in the President's condition has continued since the last bulletin. Pulse, 128; temperature, 101°; respiration, 27.

During the early morning the President slept 4 or 5 hours and his condition was satisfactory.

At 4.45 p. m., he was given a teaspoonful of water by the mouth; also an enema of sweet oil, soap and water. He passed slightly colored fluid with some little fecal matter and mucus. After this he had a small quantity of water by the mouth, and at 6.20 p. m. a nutritive enema of egg, whisky and water, which was partly retained. Digitalis and strychnin were both given during the evening.

At 9 p. m. the President was resting comfortably. The pulse was 130; temperature, 101.6°; respiration, 30.

Four hundred and twenty cc. of urine was passed during the day.

SECOND URINALYSIS.

Quantity	450 cc.
Color	amber, slightly turbid
Reaction	strongly acid

Specific gravity..... 1.026
Urea.....0.038 gm. per 1 cc. of urine
Albumin..... mere trace
Sugar.....none
Indican..... abundant
Sulphates.....increased
Phosphates.....somewhat increased
Chlorids..... somewhat increased

Microscopical Examination.—Microscopic examination of sediment obtained by centrifuge shows fewer organic elements. Some large and small epithelial cells and some leukocytes. Casts are not so abundant as yesterday and are *principally* of the small finely granular variety. There is a marked diminution in small renal epithelial cells.

Quite a quantity of large crystals of uric acid and bacteria are present.

FOURTH DAY, MONDAY, SEPTEMBER 9.

The bulletins tell the story of the fourth day.

Bulletin 17, 6 a. m.—The President passed a somewhat restless night, sleeping fairly well. General condition unchanged. Pulse, 120; temperature, 101°; respiration, 28.

Bulletin 18, 9.20 a. m.—The President's condition is becoming more and more satisfactory. Untoward incidents are less likely to occur. Pulse, 122; temperature, 100.8°; respiration, 28.

Bulletin 19, 3 p. m.—The President's condition steadily improves and he is comfortable, without pain or unfavorable symptoms. Bowel and kidney functions normally performed. Pulse, 113; temperature, 101°; respiration, 26.

Bulletin 20, 9.30 p. m.—The President's condition continues favorable. Pulse, 112; temperature, 101°; respiration, 27.

Codeia was substituted for morphia, as the pain was less. Digitalis and strychnin were stopped. Nutritive enemas were given at 3.20 a. m., at 4.30 and 10 p. m. Hot water was taken quite freely by the mouth.

Attempts to get a good movement of the bowels were successful at noon, when he had a large light-brown partly-formed stool. This followed a small dose of calomel and a high enema of oxgall.

On the whole, the President's condition improved steadily during the day. He slept a good deal and was fairly comfortable. There was no pain on pressure over the abdomen.

THIRD URINALYSIS.

Quantity received..... 540 cc.
Color.....amber, slightly turbid
Specific gravity..... 1.026
Albumin.....a trace
Indican.....not so abundant as yesterday
Urea..... 0.047 gm. per cc. of urine
Chlorids and phosphates... about normal
Sulphate.....still somewhat high
Sugar..... none

Microscopical Examination.—Microscopic examination of sediment obtained by centrifuge shows a decrease in the amount of organic elements and an increase of amorphous urates, but fewer crystals of uric acid. Casts are fewer and only the small granular and large hyaline varieties. The proportion of casts is greater. There are very few epithelial cells, mostly of renal type. A large number of cylindroids are found.

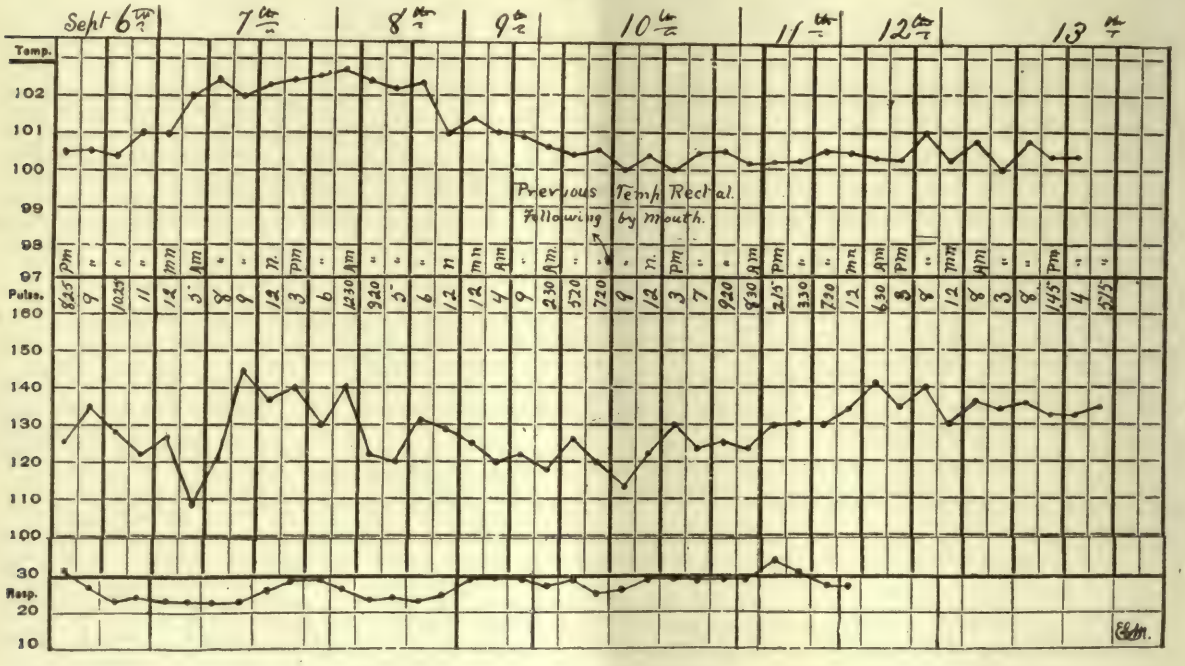
FIFTH DAY, TUESDAY, SEPTEMBER 10.

Soon after midnight the President had a high enema of soap and water, which was expelled, together, with some fecal matter. He took hot water frequently, and slept a good deal.

Bulletin 21, 5.20 a. m.—The President has passed the most comfortable night since the attempt on his life. Pulse, 118; temperature, 100.4°; respiration, 28.

On awakening he felt very comfortable, and his mind was clear and cheerful. The nutritive enemas were kept up, and water given by the mouth. Had 2 small stools during the day. The only medicine given was one hypodermic of codeia phosphate, 0.015 gm.

In the evening the dressings were examined, and as there was considerable staining from the discharge, it was thought best to remove 4 stitches and separate the edges of the wound. A little slough was observed near the bullet track, covering a space nearly an inch wide, the thickness of the flaps. The separation seemed to extend down to the muscle. The surfaces, except those mentioned, looked healthy, but not granulating. It was supposed that the infection of the wound occurred either from the bullet or from the piece of clothing carried into the wound at the time of the shooting. The parts were thoroughly washed with hydrogen dioxid and packed lightly with gauze, and held together with adhesive straps.



SIXTH DAY, WEDNESDAY, SEPTEMBER 11.

Bulletin 26, 9 a. m.—The President rested comfortably during the night. Decided benefit has followed the dressing of the wound made last night. His stomach tolerates the beef juice well, and it is taken with great satisfaction. His condition this morning is excellent. Pulse, 116; temperature, 100.2°.

Bulletin 27, 3.30 p. m.—The President continues to gain, and the wound is becoming more healthy. The nourishment taken into the stomach is being gradually increased. Pulse, 120; temperature, 100.2°.

Bulletin 28, 10 p. m.—The President's condition continues favorable. Blood count corroborates clinical evidence of the absence of any blood poisoning. He is able to take more nourishment and relish it. Pulse, 120; temperature, 100.4°.

The blood count made by Dr. Wasdin in the evening was as follows:

Leukocytes	6,752.
Red cells	3,920,000.

A little after midnight, Wednesday morning, the patient was given 4 cc. of beef juice, the first food taken by the stomach. It seemed to be very acceptable. Nutritive enema was given at 2 a. m.; later there was a yellow stool.

From 4 to 8 cc. of beef juice was given every 1 to 2 hours during the day. The rectum was becoming irritable, and did not retain the nutritive enemas well.

At 10 a. m. the remaining stitches were removed, the wound separated and dressed. It seemed to be doing well. Most of the sloughing tissue had separated.

The patient slept much during the day, and expressed himself as feeling very comfortable. The only medicine administered was one hypodermic of strychnin.

In the evening he was changed to a fresh bed. Nutritive enemas were continued.

Urine was passed much more freely—750 cc. in 24 hours.

FOURTH URINALYSIS.

Quantity	82 cc.
Color	amber, clear
Specific gravity	1.027
Reaction	strongly acid
Albumin	a trace
Indican	abundant
Urea	0.04 gm. per 1 cc. of urine
E. phosphates and chlorids	normal
Sulphates	still a little high

Microscopical Examination.—Microscopic examination of sediment obtained by centrifuge shows a marked diminution in amount of organic elements, but a great increase in uric acid crystals.

There are very few epithelial cells—mostly of renal type.

There are fewer casts—small and large hyaline—some finely granular.

Cylindroids are more abundant.

SEVENTH DAY, THURSDAY, SEPTEMBER 12.

The President slept a good deal during the night, and awoke in the morning feeling better. The beef juice was continued and increased, and a little chicken broth added to the dietary. He also had a little whiskey and water.

At 8.30 a. m. he had chicken broth, a very small piece of toast and a small cup of coffee. He did not care for the toast, and ate scarcely any of it.

The wound was dressed and washed with a weak solution of iodin and then with hydrogen dioxid. He was given 30 cc. of castor oil at 9.20 a. m.

The President now seemed at his best and his condition to warrant the favorable prognosis given out. The time for peritonitis and sepsis had passed. The bowels had moved and gas passed freely, showing that there was no obstruction. The tongue was clear, and the appetite increasing; and he seemed to be able to digest food. There was no pain nor tenderness in the abdomen, and he was able to turn easily and to sleep on his side. The urine was steadily increasing. His spirits were good and his mind clear, while his pulse, though frequent, was strong and of good quality, and the temperature low.

The analysis of the urine gave no uneasiness, as the amount of urea was fair; there was no albumin worth considering, and the casts were rapidly diminishing. There were no more of them than are found in a large percentage of cases following a long operation under ether. The excess of indican was taken to mean merely some intestinal indigestion, and to be of no serious import. The only symptom to cause any uneasiness was the frequency of the pulse. Still, anxiety on this score was relieved by knowing that the President had naturally a rapid pulse, and that it was easily excited. The open wound was not considered important. It looked healthy, and, although it would take a long time to heal, in itself it was evidently causing no harm, nor was it likely to.

Dr. McBurney left Buffalo for his home in the morning, having arranged to return at once if his presence was desired.

Toward noon it was noticed that the character of the pulse was not quite so good. Infusion of digitalis, 8 cc., was ordered, and strychnin, 0.002 gm.

It was thought probable that there was some intestinal toxemia, as there had been no free movement from the bowel since food had been begun, the oil having failed to act. Gradually the pulse went to 130, and grew weaker.

Dr. Charles G. Stockton was added to the medical staff in consultation. At 7 p. m. the President was given 0.20 gm. of calomel.

Bulletin 32, 8.30 p. m.—The President's condition this evening is not quite so good. His food has not agreed with him, and has been stopped. Excretion has not yet been properly established. The kidneys are acting well. His pulse is not satisfactory, but has improved in the last 2 hours. The wound is doing well. He is resting quietly. Temperature, 100.2°; pulse, 128.

At 9.30 p. m. a second dose of 30 cc. of castor oil was given, followed by a high enema of oxgall. This resulted in a large, dark semifluid stool, which seemed to exhaust him somewhat. Stimulants were given freely. No more beef juice or food was given. The pulse grew rapidly worse, but at midnight there seemed some improvement, as bulletin 33 shows. At 11 p. m. 420 cc. of normal salt solution was given subcutaneously.

Bulletin 33, 12 m.—All unfavorable symptoms in the President's condition have improved since the last bulletin. Pulse, 120; temperature, 100.2°.

FIFTH URINALYSIS.

Quantity	132 cc.
Color	light amber, very turbid
Specific gravity	1.025
Reaction	acid
Albumin	mere trace, if any
Indican	less
Urea	0.044 gm. per 1 cc. of urine
Sulphates	about normal
E. phosphates	much increased
Chlorids	normal

Microscopical Examination.—Microscopic examination of sediment obtained by centrifuge, shows fewer organic elements than the last examination. There is less uric acid and a large amount of amorphous phosphates. Renal casts, about as in the last examination, with very few cylindroids.

EIGHTH DAY, FRIDAY, SEPTEMBER 13.

At midnight the pulse was fairly good, 132. Strychnin and whisky were given at intervals, and hypodermics of camphorated oil.

Bulletin 34 2.50 a. m.—The President's condition is very serious, and gives rise to the gravest apprehension. His bowels have moved well, but his heart does not respond properly to stimulation. He is conscious. The

skin is warm, and the pulse small, regular, easily compressible, 126; respiration, 30; temperature, 100°.

The wound had been dressed regularly in the manner described 3 times a day. At 9 a. m. the dressing was changed, and a mixture of balsam of Peru and glycerin put in on gauze after the douching.

Stimulants were continued as before, but more freely. Coffee, 45 cc., and clam broth, 60 cc., were given; also liquid peptonoids.

At 8.30, 1.50 gm. of adrenalin was given hypodermically, and repeated at 9.40.

At 10 a. m., nearly 2 pints of normal salt solution were given under the skin, and a pint containing adrenalin at 6 p. m. Nitroglycerin and camphor were also injected at various times, together with brandy and strychnin.

Stimulants as detailed above were used freely all day.

3.30 p. m. Pulse growing weaker.

5.00 p. m. Oxygen given and continued for some hours.

6.30 p. m. Last bulletin, No. 39:

Bulletin 39, 6.30 p. m.—The President's physicians report that his condition is most serious in spite of vigorous stimulation. The depression continues and is profound. Unless it can be relieved, the end is only a question of time.

At 6.35 p. m., and again at 7.40, morphin was given hypodermically, as he was very restless and seemed to be suffering.

9.00 p. m. Heart sounds very feeble.

The President continued to sink, becoming weaker and weaker.

At 10.00 p. m., the oxygen was discontinued. The heart sounds were very feeble and consciousness lost.

The President died at 2.15 a. m., September 14.

Drs. E. J. Janeway and W. W. Johnston, who, at the request of Dr. Rixey, had been summoned in consultation, arrived too late, but were present at the autopsy. Dr. McBurney also returned on Friday afternoon.

SIXTH URINALYSIS.

Color	amber, turbid, with phosphates
Quantity	252 cc.
Reaction	acid
Specific gravity	1.023
Albumin	mere trace, if any
Urea	0.047 gm. per 1 cc. urine
Indican	a trace
E. phosphates	increased
Chlorids	normal
Sulphates	a little high

Microscopical Examination.—Microscopical examination of sediment obtained by centrifuge, before and after clearing, shows no change from yesterday's sample. Casts, hyaline and granular, both large and small, comparatively few. Cylindroids, a few. Crystals, large amount of uric acid, some sodium urate, and in the untreated specimen a large amount of amorphous deposit, principally of phosphates. There are a few epithelial cells, small, granular. Occasional red cells and leukocytes.

REPORT ON THE AUTOPSY.[1]

BY HARVEY R. GAYLORD, M.D.

Ordinary signs of death: ecchymosis in dependent portions of the body. Rigor mortis well marked. Upon the surface of the chest, to the right of the midsternal line, a spot 1 cm. in diameter, dark-red in color, with a slight crust formation covering it, 5.5 cm. from the suprasternal notch; from the right nipple, 10 cm.; from the line of the right nipple, 8.25 cm. Surrounding this spot, at which point there is an evident dissolution of the continuity of the skin, is a discolored area of oval shape extending upward and to the right. In its greatest length it is 11 cm.; and in its greatest width, 6 cm. It extends upward in the direction of the right shoulder. The skin within this area is discolored, greenish-yellow and mottled.

The surface of the abdomen is covered with a surgical dressing, which extends down to the umbilicus and upward to just below the nipples. The innermost layer of cotton is covered or stained with balsam of Peru and blood. On removing this dressing, a wound, parallel to, and somewhat to the left of, the median line, is exposed, inserted in which are 2 layers of gauze, likewise impregnated with balsam of Peru. The wound is 14.5 cm. in length, and is open down to the abdominal muscles. The layer of abdominal fat is 3.75 cm. in thickness. The appearance of the fat is good, a bright yellow in color. No evidence of necrosis or sloughing. In the left margin of the surgical wound, lying 1 cm. to the right of a line drawn from the umbilicus to the left nipple, 15.5 cm. from the nipple and 16.5 cm. from the umbilicus is a partly healed indentation of the skin, and an excavation of the fat immediately beneath it (this is the site of the entry of the bullet), extending down to the peritoneal surface. On making the median incision, starting from the suprasternal notch and extending to a point just below the symphysis, the subcutaneous fat is exposed, which is of bright yellow color and normal appearance except in an area which corresponds superficially to the area of discoloration described as surrounding the wound upon the chest wall. This area marks the site of a hemorrhage into the subcutaneous fat. The remainder of the subcutaneous fat is firm and measures 4.75 cm. in thickness on the abdominal wall. On opening the sheath of the right rectus muscle, it is seen to be of dark-red color. (Culture taken from ecchymotic tissue under the upper bullet hole and from between the folds of the small intestine. Three tubes from each locality on agar and gelatin.)

On opening the abdominal cavity, the parietal surface of the peritoneum is exposed, and is found to be covered with a slight amount of bloody fluid; is perfectly smooth and not injected. The great omentum extends downward to a point midway between the umbilicus and the symphysis. It is thick, firm; its inferior border is discolored by coming in contact with the intestines. Below the umbilicus a few folds of intestines are exposed. These are likewise covered with discolored blood, after the removal of which the peritoneal surface is found to be shiny. On the inner aspect of the abdominal wound the omentum is found to be slightly adherent to the parietal peritoneum, and can be readily separated with the hand from the edge of the wound. At this point the omentum is somewhat injected. This adhesion to the omentum is found to extend entirely around the abdominal wound. The parietal peritoneum immediately adjacent to the inner aspect of the abdominal wound is ecchymotic.

On removing the subcutaneous fat and muscles from the thoracic wall, the point which marks the dissolution of continuity of the skin upon the surface, is found to lie directly over the margin of the sternum and to the right side between the second and third ribs. There is no evidence of ecchymosis or injury to the tissues or muscles beneath the subcutaneous fat. On making an incision through the subcutaneous fat, directly through the wound upon the chest, a small cavity is exposed about the size of a pea just beneath the skin which is filled with fluid blood. The subcutaneous tissue underlying the area of discoloration on the surface of the chest wall shows hemorrhagic infiltration.

On removing the sternum, the lungs are exposed, and do not extend far forward. A large amount of pericardial fat is exposed. Pleural surface on both sides is smooth. There are no adhesions on either side within the pleural cavities. The diaphragm on the right side extends upward to a point opposite the third rib in the mammary line. No perceptible amount of fluid in either pleural cavity. On opening the pericardial cavity, the surface of the pericardium is found to be smooth and pale. The pericardium contains approximately 6 cc. of straw-colored, slightly turbid fluid. (Some taken for examination.)

On exposing the heart, it is found covered with a well-developed panniculus. The heart measures, from the base to the apex, on the superficial aspect, 10.5 cm. The right ventricle is apparently empty. The heart feels soft and flaccid. On opening the left ventricle, a small

[1] The autopsy was performed by Drs. Gaylord and Matzinger of the New York State Pathological Laboratory.

amount of dark-red blood is found. The muscle of the left ventricular wall is 1.5 cm. in thickness; dark reddish-brown in color; presents a shiny surface. The average thickness of the pericardial fat is 3.5 mm. (Cultures made from the auricle.) The left auricle contains but a small amount of dark currant-colored blood. The mitral valve admits 3 fingers. The right ventricle, when incised in the anterior line, is found to be extremely soft; the muscular structure is 2 mm. in thickness. The panniculus measures 7 mm. The muscle is dark red in color; very shiny, and the pericardial fat invades the muscular wall at many points.

On opening the right auricle it is found to be filled and distended by a large currant-colored clot, which extends into the vessels. The tricuspid orifice admits readily 3 fingers. The coronary arteries are patulous and soft; no evidence of thickening.

Lungs are gray color, and contain a moderate amount of coal-dust pigment. Slight amount of frothy fluid escapes from the bronchi; but the pulmonary tissue is crepitant and free from exudate.

On unfolding the folds of intestine, there is no evidence of adhesion until a point just beneath the mesocolon is reached, when, on removing a fold of small intestine, a few spoonfuls of greenish-gray thick fluid flows into the peritoneal cavity.

On the anterior gastric wall is an area to which a fold of the gastrocolic omentum is lightly adherent. On breaking the adhesion there is found a wound about midway between the gastric orifices, 3.5 cm. in length, parallel with the greater curvature of the stomach, 1.5 cm. from the line of omental attachment. This wound is held intact by silk sutures. There is no evidence of adhesion at any other point on the anterior wall. The gastric wall surrounding the wound just mentioned for a distance of 2 cm. to 3 cm. is discolored, dark greenish-gray in appearance, and easily torn. On exposing the posterior wall of the stomach from above, along its greater curvature, the omentum is found to be slightly adherent, a line of silk ligatures along the greater curvature of the stomach marking the site where the omentum had been removed. On throwing the omentum downward, the posterior gastric wall is exposed. On the posterior wall, a distance of 2 cm. from the line of omental attachment, is a wound approximately 2 cm. long, held intact by silk sutures. The gastric wall surrounding this wound is discolored. On the surface of the mesocolon, which is posterior to the gastric wall at this point, is a corresponding area of discoloration, the portion coming directly in contact with the wound in the gastric wall being of dull gray color. The remainder of the surface of the posterior wall of the stomach is smooth and shiny. Beyond the surgical wound in the posterior wall of the stomach is found an opening in the retroperitoneal fat, large enough to admit 2 fingers. This opening communicates with a track which extends downward and backward as far as the finger can reach. The tissues surrounding this track are necrotic . On removing the descending portion of the colon, a large irregular cavity is exposed, the walls of which are covered with gray, slimy material, and in which are found fragments of necrotic tissue. Just at the superior margin of the kidney is located a definite opening which forms the bottom of the track traced from the stomach. On stripping the left kidney from its capsule, it is found that the superior portion of the capsule is continuous with the cavity. The weight of the left kidney is 5 oz. 1 gr. The kidney is readily stripped from its capsule; is dark red; the stellate veins are prominent, and along its greater curvature are numerous dark red depressions. On the superior aspect of the kidney is a protrusion of the cortex, dark red in color, and in this protrusion is a laceration 2 cm. long, extending across the superior border, approximately at right angles to the periphery of the kidney and from before backward. On incising the kidney, the cortex and medulla are not easily distinguishable from one another; both are of rose-red color, the cortex measuring approximately 6 mm. in thickness. The vessels in the pyramids of Ferrein are very prominent. Beneath the protruding portion of the surface, the cortex is dark red in color. This discoloration extends downward in pyramidal form into the medulla. The laceration of the surface marks the apex of the protrusion of the kidney substance. Between the spleen and the superior aspect of the kidney is a necrotic tract which extends down and backward, and ends in a blind pocket. The tract which included the superior aspect of the kidney can be traced into the perinephritic fat to a point just above the surface of the muscles of the back.

The necrotic cavity which connects the wound on the posterior wall of the stomach and the opening adjacent to the kidney capsule is walled off by the mesocolon, and is found to involve an area of the pancreas, approximately 45 mm. in diameter and extending about half-through the organ. This organ at its center forms part of the necrotic cavity. Through its body are found numerous minute hemorrhages and areas of gray softening, the size of a pea or smaller. These are less frequent in the head portion of the pancreas.

A careful examination of the track leading down toward the dorsal muscles fails to reveal the presence of any foreign body. After passing into the fat, the direct character of the track ceases, and its direction can be traced no further. The adjoining fat and the muscles of the back were carefully palpated and incised, without disclosing a wound or the presence of a foreign body. The diaphragm was carefully dissected away, and the posterior portion of the thoracic wall likewise carefully examined. All fat and organs which were removed, including the intestine, were likewise examined and palpated, without result.

The great amount of fat in the abdominal cavity and surrounding the kidney rendered the search extremely difficult.

The right kidney is imbedded in a dense mass of fat; capsule strips freely; it weighs 5 ounces; measures 11.5 cm.; substance is soft; cortex is 6 mm. in thickness; rose-red in color; cut surface slightly dulled. There are a few depressions of the surface, and the stellate veins are prominent.

The liver is dark-red in color; the gall-bladder distended. The organ was not removed.

The autopsy continued for a longer period than was anticipated by those who had charge of the President's body, and we were requested to desist seeking for the bullet and terminate the autopsy. As we were satisfied that nothing could be gained by locating the bullet, which had apparently set up no reaction, search for it was discontinued.

Anatomical Diagnosis.—Gunshot wound of both walls of the stomach and the superior aspect of the left kidney; extensive necrosis of the substance of the pancreas; necrosis of the gastric wall in the neighborhood of both wounds; fatty degeneration, infiltration and brown atrophy of the heart muscle; slight cloudy swelling of the epithelium of the kidneys.

A matter of no inconsiderable embarrassment to us arose in the objection to our removing sufficient portions of the tissues for examination. We were able to secure only 2 small fragments of the stomach wall; tissue from around the wound upon the chest well; a portion of fat from the wall of the necrotic cavity; a small piece of each kidney, that of the left kidney including the portion involved by the original wound; and pieces of heart-muscle from the right and left ventricles. The microscopical examination of these tissues follows:

The piece of retroperitoneal fat, where it forms part of the necrotic cavity, is seen on section to be covered with a thick gray deposit, which has an average thickness of from 4 mm. to 6 mm. Beneath this, and separating it from the fat, is a well-defined area of hemorrhage from 1 mm. to 2 mm. in thickness. The appearance of this piece of tissue is characteristic of the fat tissue surrounding the entire cavity. A section made perpendicular to the surface and stained with hematoxylin-eosin, shows the following characteristics: Under low power there is no evidence of round-celled infiltration between the fat cells, or of fat necroses. The surface of the tissue which, in the microscopical specimen was covered by a layer of grayish material, proves, under low power, to consist of a partly organized fibrinous deposit. At the base of this deposit is evidence of an extensive hemorrhage, marked by deposits

of pigment. The surface of the membrane is of rough and irregular appearance, and contains a large number of round cells with deeply stained nuclei. Under high power the organization of the membrane may be traced from the base toward the surface. The portion immediately adjacent to the fat tissue consists of a network of fibrin enclosing large numbers of partly preserved red blood corpuscles. In many areas the red blood corpuscles are broken down and extensive deposits of pigment are found. Extending into the fibrin structure of the membrane are numerous typical fibroblasts and round cells. In some regions pigment is evidently deposited in the bodies of large branching and spindle cells. Here and there, included in the membrane, are the remains of fat cells, and toward the surface of the membrane a large number of round cells scattered through the interstices of the membrane. There are but few polymorphonuclear leukocytes. Here and there in the membrane are fragments of isolated fibrous connective tissue with irregular contours and an appearance suggesting that they are fragments of tissue which have been displaced by violence and included in the fibrin deposit. The fibrin in the superficial layers of the membrane is formed in hyaline clumps. The organization along the base of the deposit is comparatively uniform.

Sections stained with methylen blue, carbol-thionin and Gram's method were carefully examined for the presence of bacteria, with negative results. Even upon the surface of the membrane there are no evidences of bacteria.

The section of the left kidney including the triangular area of hemorrhage described in the macroscopical specimen, reveals the following appearances. (Section hardened in formalin, stained with hematoxylin-eosin.) Examined macroscopically, section represents a portion of a kidney cortex made perpendicular to the surface of the cortex, and including an area of hemorrhage into the substance of the cortex 1 cm. in length, measured from the capsular surface downward, and presenting a width of from 5 mm. to 6 mm. The capsular surface has apparently been torn.

Under low power the margins of the preparation are found to consist of well preserved kidney structure. There is a slight amount of thickening of the interstitial tissue, and occasional groups of tubules are affected by beginning cloudy swelling. The glomeruli are large and present a perfectly normal appearance. As we approach toward the center of the preparation, occasional glomeruli are met with in which the capillary loops are engorged and the adjacent tubules contain red blood-corpuscles. A short distance further, the kidney structure becomes entirely necrotic. Here and there the remains of tubules may be made out, and these are infiltrated with cells. The necrotic area presents a rough, net-like structure. As we approach toward the surface of the kidney, we find that the necrosis becomes more marked. There is the merest suggestion of kidney structure, its place being taken by disintegrated red blood-cells and leukocytes, embedded in a well-defined fibrinous network. There is great distortion of the kidney structure about the periphery of the necrotic area. In this region a considerable amount of pigment is also found in the necrotic tissues.

Under high power, the characteristics of the necrotic tissues may be better observed. The kidney structure is broken up and torn into irregular fragments, infiltrated by red blood corpuscles and leukocytes. In the portion of the necrotic mass beneath the capsule, the kidney structure is practically obliterated and is replaced by a network of fibrin, which includes large numbers of red blood-cells and leukocytes. Scattered through the entire necrotic area are frequent deposits of pigment. In the deeper portions of the necrotic area, the margins of the fibrin deposit are invaded by fibroblasts from the connective tissue structure of the kidney. The organization in these areas is, however, slight.

Sections stained with methylen-blue and Gram's method and carefully examined under oil immersion, fail to reveal the presence of any organisms. In preparations stained with methylen blue, the deposits of pigment may be readily observed. Section of the same tissue hardened in Hermann's solution and examined for fat, shows the presence of numerous fat droplets within the epithelium of the tubules which are adjacent to the area of necrosis. In the portions of the preparation more widely distant from the area of necrosis, no fat is present.

Section of the right kidney hardened in formalin and stained with hematoxylin-eosin, reveals the presence of areas in which slight parenchymatous degeneration of the epithelium in the uriniferous tubules may be noted. These areas are not extensive, and are confined to single groups of tubules. The interstitial connective tissue of the organ seems to be slightly increased in amount, but there is no well-defined round-celled infiltration. An occasional hyaline glomerulus is to be met with in these cases surrounded by increased connective tissue. The epithelium of the kidney tubules, aside from those in which the parenchymatous degeneration is present, is well preserved. The nuclei are well stained; protoplasm, finely granular.

A fragment of the stomach wall taken from the immediate neighborhood of the anterior wound is in a condition of complete necrosis. The nuclei of the cells are scarcely demonstrable. The epithelial surface is recognized with difficulty. At its base are apparently a few round cells. Examination of the blood vessels reveals nothing characteristic. There is apparently no evidence of thrombosis. A section made through the gastric wall at some distance from the wound, reveals the well-preserved muscular structure of the gastric wall, which presents no characteristic alterations. Superficial portions of the epithelium have apparently been affected by postmortem digestion. However, in one portion of the preparation, the epithelium is intact, and shows distinct evidence of marked round-celled infiltration between the glandular structures. The blood-vessels contained blood-corpuscles with the usual number of leukocytes.

The fragments of heart-muscle which were removed from the right and left ventricular walls, were examined in the fresh state, and exhibited a well-defined fatty degeneration of the muscle fibers, and in the case of the right ventricular wall, an extensive infiltration between the muscle fibers, of fat, was apparent. Sections from these fragments of muscle hardened in Hermann's solution, are taken for examination. A fragment of muscle from the right ventricular wall was removed at a point where the fat penetrated deeply into the muscular structure, the ventricular wall at this point showing an average thickness of 2.5 mm. Under low power, the muscle fibers are separated into bundles by masses and rows of deeply fat cells. The muscle fibers are seen to contain groups of dark brown granules lying in the long axes of the cells. Under high power, these are resolved into extensive groups of dark brown pigment arranged around the nuclei. The muscle fibers are slender, the cross and longitudinal striation is well-defined. Examined near the margin of the preparation, where the osmic-acid fixation has been successful, all of the muscle fibers are found to contain minute black spherical bodies, extending diffusely through all the muscle fibers about the entire margin of the preparation. These fine fat droplets are present in sufficient amount to speak of an extensive diffuse fatty degeneration of the muscle fibers. Where the large fat cells have separated the muscle fibers, these are found to be more atrophic than those in the central portions of the larger bundles.

The examination of the section through the healed bullet wound on the chest walls reveals nothing of importance. The dissolution of continuity is filled in by granulation-tissue, and there is evidence of beginning restoration of the epithelium from the margins. Stains for bacteria give negative results.

To sum up: The macroscopical and microscopical findings of the autopsy, may be stated, as follows: The original injuries of the stomach-wall had been repaired by suture, and this repair seems to have been effective. The stitches were in place, and the openings in the stomach-wall effectually closed. Firm adhesions were formed both upon the anterior and posterior walls

of the stomach, which reinforced these sutures. The necroses surrounding the wounds in the stomach do not seem to be the result of any well-defined cause. It is highly probable that they were practically terminal in their nature, and that the condition developed as a result of lowered vitality. In this connection there is no evidence to indicate that the removal of the omentum from the greater curvature and the close proximity of both of these wounds to this point, had any effect in bringing about the necrosis of the gastric wall, although circulatory disturbances may have been a factor. The fact that the necrotic tissue had not been affected by digestion strongly indicates that the necrosis was developed but shortly before death. The excavation in the fat behind the stomach must be largely attributed to the action of the missile. This may have been the result of unusual rotation of a nearly spent ball, or the result of simple concussion from the ball passing into a mass of soft tissues. Such effects are not unknown. The fact that the ball grazed the superior aspect of the left kidney, shown by the microscopic investigation of that organ, indicates the direction of the missile, which passed in a line from the inferior border of the stomach to the tract in the fat immediately superior to the kidney. There was evidence that the left adrenal gland was injured.

The injury to the pancreas must be attributed to indirect, rather than direct, action of the missile. The fact that the wall of the cavity is lined by fibrin, well advanced in organization, indicates that the injury to the tissues was produced at the time of the shooting. The absence of bacteria from the tissues, indicates that the wound was not infected at the time of the shooting, and that the closure of the posterior gastric wound was effectual. The necrosis of the pancreas seems to us of great importance. The fact that there were no fat necroses in the neighborhood of this organ, indicates that there was no leakage of pancreatic fluid into the surrounding tissues. It is possible that there was a leakage of pancreatic fluid into the cavity behind the stomach, as the contents of this cavity consisted of a thick, grayish fluid, containing fragments of connective tissue. In this case the wall of fibrin would have been sufficient to prevent the pancreatic fluid from coming in contact with the adjacent fat. The extensive necrosis of the pancreas would seem to be an important factor in the cause of death, although it has never been definitely shown how much destruction of this organ is necessary to produce death. There are experiments upon animals upon record, in which the animals seem to have died as a result of not very extensive lesions of this organ. One experiment of this nature reported by Flexner (*Journal of Experimental Medicine*, Vol. II) is of interest. The fact that concussion and slight injuries of the pancreas may be a factor in the development of necrosis, is indicated by the researches of Chiari (*Zeitschrift fur Heilkunde*, Vol. XVII., 1896, and *Prager Med. Wochenschr.*, 1900, No. 14), who has observed (although a comparatively rare condition) extensive areas of softening and necrosis of the pancreas, especially of the posterior central portion which lies directly over the bodies of the vertebra, where the organ is most exposed to pressure or the effects of concussion. The wound in the kidney is of slight importance, except as indicating the direction taken by the missile. The changes in the heart, as shown by the macroscopic inspection and the microscopic examination, indicate that the condition of this organ was an important factor. The extensive brown atrophy and diffuse fatty degeneration of the muscle, but especially the extent to which the pericardial fat had invaded the atrophic muscle fibers of the right ventricular wall, sufficiently explain the rapid pulse and lack of response of this organ to stimulation during life.

REPORT ON THE BACTERIOLOGICAL EXAMINATION.

BY HERMAN G. MATZINGER, M.D.[1]

It is obvious that the short space of time which has elapsed since the death of the President has hardly been sufficient to prepare a complete and thorough bacteriological report. This report contains all the observations which have been made up to this time:

On September 11th, during the life of the President, cultures were made by Dr. Wasdin from the base of the abdominal wound and from dressings removed at the same time. These were submitted to me for examination, and showed the presence of the ordinary pus organisms: *Staphylococcus pyogenes aureus* and *Staphylococcus cereus albus*, with a gas-forming bacillus which, in pure anaerobic culture on glucose gelatin, forms small, pearly, translucent colonies, with no liquefaction. In litmus milk it produces acid, but no coagulation. Morphologically, it is apparently a capsulated, short bacillus, which takes stains poorly, and which does not stain by Gram's method. Inoculated into the ear vein of a rabbit, which was killed immediately afterward, it produced, after 24 hours in the body of the rabbit, a marked accumulation of gas in the organs, and again grew out in pure culture. As yet the organism is not fully identified.

None of these cultures showed streptococci. A *bacterium* which appears to be one of the proteus group was, however, isolated, which does not stain by Gram, and appears in varying forms, sometimes small oval, and again quite rod-shaped and in short chains. Sometimes it is surrounded with a slimy covering, which remains clear like a capsule when the organism is stained. On slanting agar, it produces a whitish, slimy growth, which gradually runs to the bottom of the slant and produces an odor of decomposition. On gelatin, it grows very slowly with slight and slow indication of liquefaction. In litmus milk, it produces acid and rapid coagulation.

At the time of the autopsy, September 14th, inoculations were made by myself. From the base of the wound, there was again obtained a number of pus organisms, principally a white staphylococcus and the bacterium described above, but no streptococci. Cultures made from the peritoneal surface of the intestines were entirely negative. Cultures made from the under surface of the omentum near the colon, were entirely negative, both with and without oxygen. Cultures from the blood of the right auricle were likewise negative. A very careful and extensive search for micro-organisms in the contents of the necrotic cavity, behind the stomach, reveals nothing but a short stumpy bacterium, which, as far as the work has been carried at present appears to belong to the proteus group, and is very like *Proteus hominis capsulatus*, described by Bordoni and Uffreduzzi.

Morphologically, it is not uniform, and sometimes appears almost encapsulated, being surrounded by material that does not stain; is quite refractory to Gram, and produces an odor of decomposition as it grows. It does not liquefy gelatin rapidly and grows slowly, as a glistening white elevated surface growth which slowly sinks; but on agar in the thermostat it grows very rapidly, as a moist, grayish-white, translucent mass. Colonies on gelatin plates have a clean circumference, are granular and quite refractive. In litmus milk it produces acid and rapid coagulation. Animal experiments are still incomplete and cannot be published at this time.

It must be stated that there is occasion for suspecting that this may be a contamination, either from the outer wound or elsewhere, because, quite unavoidably, the technic of obtaining the material and cultures from the necrotic cavity was not absolutely correct.

Cultures made from the small area of broken-down tissue under the chest wound at the time of the autopsy, grew what appears to be *Staphylococcus epidermidis albus*, described by Dr. Welch.

The slimy, gray, necrotic material from the cavity above the transverse mesocolon behind the stomach, was carefully examined microscopically, with the result that very few micro-organisms were found in the fresh state, and no recognizable tissue elements of any kind, no leucocytes or pus-corpuscles, but an abundance of crystals which appeared more like fatty acid than fat crystals. It contained no free hydrochloric acid, and was alkaline in reaction. Experiments as to its digestive power were negative. About 2 cc. of this material

[1] Bacteriologist to the New York State Pathological Laboratory.

was injected into the space behind the stomach of a dog (still living), with no results except quite an elevated temperature for 3 or 4 days. Other animal experiments are also still incomplete.

It might be well to state here that the bacteriological examination of the chambers and barrel of the weapon used, as well as the empty shells and cartridges, ordered by the District Attorney, was entirely negative, except that from a loaded cartridge there was grown an ordinary staphylococcus and a mould. The chemical examination of the balance of the loaded cartridges, made by Dr. Hill, chemist, was also negative.

The absence of known pathogenic bacteria, particularly in the necrotic cavity, warrants the conclusion that bacterial infection was not a factor in the production of the conditions found at the autopsy.

VIRCHOW'S BIRTHDAY CELEBRATION.

IT IS a pleasant thought that the American medical fraternity has honored itself in honoring Dr. Rudolf Virchow in a fitting testimonial held in New York last Saturday night. In so doing they have allied themselves with the medical world of Europe in deed as well as in spirit and have made manifest to the followers of science that its borders are universal and its masters are recognized as readily and honored as heartily in this, the New World, as in the Old.

THE VIRCHOW DINNER

AT SHERRY'S,

Fifth Avenue and Forty-fourth Street,
Saturday, October 12th, 1901,

AT SEVEN P. M.

J. D. BRYANT CHAS. L. DANA
A. JACOBI ANDREW H. SMITH
WM. H. THOMSON.

Committee.

This is the simple announcement that drew together over 100 representative medical men of the country and many others were present in thought if not in body. The list of those who attended or contributed is as follows:

Drs. I. Adler, S. Alexander, J. M. Anders, A. C. Abbot, C. Beck, A. B. Ball, J. D. Bryant, J. Byrne, C. E. Bruce, J. F. Bell, L. F. Bishop E. F. Brush, J. F. Chauveau, W. F. Chappell, C. N. B. Camac, John G. Clark, W. H. Carmalt, E. K. Dunham W. W. Dold, Ch. L. Dana, Judson Daland, F. W. Dercum, M. Einhorn, C. A. Elsberg, E. D. Fisher, N. A. Fairbairn, C. B. Fitzpatrick, J. Fuhs, G. R. Fowler, Simon Flexner, A. Gerster, A. L. Goodman, G. M. Gould, Henry Hun, H. A. Hare, Henry M. Hurd, W. S. Halstead, T. W. Hastings, J. E. Ill, M. P. Jacobi, Ch. Jewett, W. James, G. W. Jacoby, S. E. Jelliffe, A. Jacobi, E. G. Janeway, W. B. Johnson, W. H. Katzenbach, S. A. Knopf, C. I. Kipp, G. Langmann, F. Lange, F. Leviseur, S. J. Meltzer, J. C. McCoy, John P. Munn, Walter Mendelson, Alfred Meyer, J. H. Musser, W. G. McCollum, Paul F. Munde, Phillip Marvel, Robert A. Murray, Ferd. S. McHale, W. P. Northrup, J. D. Nisbet, William Osler, E. L. Opie, Charles N. Packard, Edw. S. Peck, W. M. Polk, J. Rudisch, A. R. Robinson, B. Robinson, T. M. Rotch, M. H. Richardson. M. R. Richards, M. A. Starr, F. A. Sondern, R. Sayre, A. A. Smith, D. M. Stimson, George F. Shrady, R. A. Sands, A. H. Smith, B. Sachs, A. Stengel, F. J. Shattuck, Theo. Smith, W. H. Thomson, John S. Thacher, James Tyson, H. N. Vineberg, J. A. Wyeth, F. W. Wunderlich, J. H. Wiggin, R. G. G. Wiener, L. Weber, William Welch, J. C. Wilson.

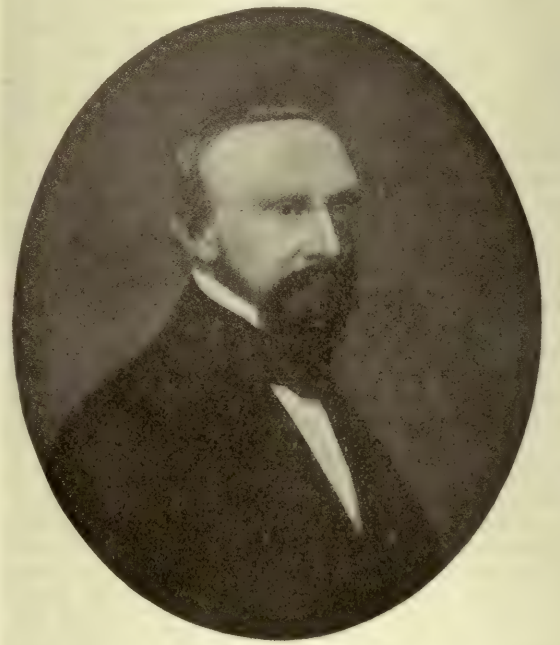
The menu was a pleasing surprise to the guests, reproducing on the outside cover, in the familiar green Virchow's *Archiv für pathologische Anatomie.*

Within were two portraits, one of Virchow when thirty-eight years old, presented by the eminent scientist to Dr. Andrew H. Smith, of this city. We here reproduce it. A later portrait was also given as per the second illustration offered to the readers of the MEDICAL NEWS.

The toasts were few, but were of great interest.

Dr. William Osler of Baltimore acted as chairman and spoke of Virchow as a scientist, especially along the lines of anthropology and public health.

This night, he said, was a notable one, in that eighty years ago it gave birth to one of the great lights of modern science, and it was



Virchow in 1859.

a night that marked a boundary of eighty years of almost unparalleled scientific activity. Genius, he remarked, has been said to be a matter of environment and of birth and in both respects Virchow could be said to have been most fortunate. It had been his great opportunity to have been a pupil of Johannes Müller, and the spirit breathed into the pupil was later expressed by him in his own address on Johannes Müller, his teacher, at the time of the latter's death. Scientific pathology, he then wrote, was at the time of Müller still struggling to free itself from the vague mysticism of the later empirics; conceptions of disease were theoretical and it was Müller's great service to have brought back into medical science the spirit of early Greek medicine. Observation, study and analysis had been the mainspring of these early Greek philosophers and this spirit had slumbered for at least fourteen hundred years until the sleep of idle

speculation had been broken by Vesalius in anatomy. But in pathology it had been Müller who had been the apostle of observation to bring into active life the just awakening science.

It is surprising, said Dr. Osler, speaking of his work in anthropology, that he should have been so prolific in studies, and these were not the work of a mere dilettante, dabbling in skulls and in relics, but those of a recognized master. He was conversant with all of the important research work going on in the field.

Illustrating his great interest in this line of work, also casting a side light on the spirit of the man, Dr. Osler said that at one time desiring to present him with something that he thought Virchow would like, he obtained the help of some of his friends on the Canadian Geological Survey, who procured for him some skulls of the British Columbian Indians. These he presented to Dr. Virchow, who was delighted to get them. He recognized them, knew all about them and kept his students waiting while he pointed out their most interesting archeological features, contrasting them with other skulls derived from far distant lands and from prehistoric peoples.

Of his contributions to the science of hygiene his "Gesammelte Abhandlungen" give testimony of great application and virility. He was an ardent and fertile student. No other worker on these problems, save, perhaps, Pettenkofer, could be said to have made such radical changes in the then prevailing mismanagement of municipal health affairs. The city of Berlin owes much of its present excellent sanitary system to his labors.

Dr. Osler then proposed a toast to the master which was responded to with a hearty "Drei mal hoch."

Dr. Gould then read a cablegram to be sent to Dr. Virchow which said that 100 of his medical friends and admirers were gathered in New York to drink his health and wish him continued years of usefulness.

Virchow as a Pathologist.—Dr. William H. Welch of Baltimore then gave an excellent response to this toast. He said: "We are here to-night to honor a man whose services to science, to truth, and to humanity, are immeasurable, and in so doing we honor ourselves. It has been said that whoever would undertake to give a comprehensive picture of the life and work of Rudolf Virchow should be a genius approaching in universality Virchow himself. Hence it is that attempts to estimate the work of this great master, its different aspects—pathological, anthropological, hygienic, political, and other—must be assigned to different speakers or writers. I have been asked to speak more particularly of Virchow's work in pathology, but it would be proposterous to attempt to give in an after-dinner talk even in barest outline an estimate of his manifold activities in this large field. All that I can hope to do is to present certain features which seem to me of especial significance, leaving untouched many others of equal importance.

"Virchow's work as an investigator began in the fifth decade of the last century, at a time when medicine was struggling to free herself from the bondage of dogmas and speculative systems, which had followed one another for centuries. The sciences collateral to medicine, such as chemistry, comparative anatomy, embryology and physiology, had already entered upon the new paths of exact observation and experiment. Gross pathological anatomy had been

Rudolf Virchow.

cultivated with enthusiasm and marked success since the beginning of the century, first in France and later in Vienna, but so erroneous were the deductions drawn therefrom, in relation both to general pathology and to clinical medicine, that its influence, reformatory as it was in certain directions, was in others positively injurious to practical medicine. With the exception of Müller's important histological study of tumors, published in 1838, there had been scarcely any fruitful application of the microscope to pathology.

"Meager as were his facilities for pathological study at the start under Robert Froriep, nevertheless Virchow's surroundings at that time must have been in many ways inspiring. The spirit of reform had begun to stir in nearly all fields of human activity. Never before had there gathered in one place

such a band of young, enthusiastic and productive workers in science, as were assembled about this time in Berlin in the laboratory of Johannes Müller, the greatest physiologist and teacher of biological science of the first half of the century, Virchow, Simon, Reinhardt, Meyer, Remak, Traube, Du Bois-Reymond, Brücke, Helmholtz. These were men all destined to become great investigators, some of them reformers in their special fields.

The directions first followed by Virchow in his pathological investigations were most fortunate and calculated to lead a man of his originality and clear insight to new points of view of fundamental importance. His earliest studies were of the chemistry and morphology of the blood, then of inflammation, and soon afterward of the connective tissues. He was thus brought at once face to face with problems which we still recognize as of the most far-reaching significance in pathology. The work which marks the culmination of the first Berlin and early Würzburg periods of Virchow's studies is that upon thrombosis and embolism—an epochal work which introduced a practically new and important chapter into pathology. The series of papers upon this subject collected in Virchow's "Gesammelte Abhandlungen" should be studied by medical students as models of exact observation, ingenious and well devised experimentation, and correct generalization. Here at last instead of speculations based upon incomplete knowledge of the facts we have the methods of the natural and physical sciences applied to problems of practical and scientific medicine.

"But Virchow was already engaged in those researches which led to the foundation of cellular pathology and which establish him as the greatest of reformers in scientific medicine. The underlying facts and principles of cellular pathology were worked out by Virchow in the early fifties while in Würzburg, but they did not become the common property of the medical world before the publication of his classic on "Cellular Pathology" in 1858. It would lead too far to attempt to rehearse here the steps which led to this great discovery. The story is an interesting one and has been told by Virchow himself in its main outlines in the opening article of the one hundredth volume of his *Archiv.* Suffice it to say that there were struggles and controversies before the universal acceptance of the great truth formulated by Virchow—*Omnis cellula e cellula.*

"We are so habituated to think in terms of the cell that it is difficult to put ourselves back even in thought to a time when pathological views were based upon the conceptions of plastic exudates and formative blastemata. The establishment of the principles of cellular pathology marked the greatest advance which scientific medicine had made since its beginning. Cellular pathology is the foundation upon which the stately superstructure of modern medicine is built. It is not a dogma, a doctrine of the schools, to be superseded by some new speculation, but it is a great biological principle. It places medicine in the rank of the biological sciences, and permits its fruitful cultivation by methods common to all natural sciences. It is to the pathologist what the atomic theory is to the chemist, what the mechanical equivalent of heat and the theory of the ether is to the physicist. It is even more than these, for we can see and study cells. It has opened up new and limitless fields of investigation which as yet have been explored only in relatively small part, and each new stone is added to the building without a quiver in the foundations.

"It is true that the last word has not been spoken in our efforts to penetrate to the finest structural elements affected by disease. There are doubtless ultimate formed and definite constituents within the protoplasm of cells, and it would he hazardous to predict to what point future investigations may lead in the understanding of their relation to the cell and their demonstrable participation in disease, but thus far there is no evidence to warrant us to regard these intracellular elements as independent, vital units in the sense in which we look upon the cell as unit. The seats of disease were transferred first from regions to organs by Morgagni, thence to the tissues by Bichat, and finally to the cells by Virchow, and there they are likely to remain, however far the analysis of the structure of the cell may be carried.

"It is impossible on this occasion to attempt to follow further the special pathological investigations of Virchow, to speak even of his monumental work on tumors. Such an attempt would lead us into every corner of pathology, for it is characteristic of the man that there is no pathological subject, however trivial at the time it may seem, which has not his interest and is not attacked by him with the same painstaking zeal as the most important one.

"There are two or three general considerations relating to Virchow's attitude and work to which I should like briefly to refer, familiar as they must be to you all.

"One is the thoroughness of Virchow's investigation of whatever subject he has taken in hand. His are no half-finished, 'preliminary communications,' launched prematurely in fear of anticipation of his results by some fellow worker, but with complete, critical command of all that his predecessors, not merely those of yesterday, may have done, and with due acknowledgment of their work, he presents in an orderly, concise and clear manner the results of his own investigations, based upon a thorough study of all the facts pertinent to the subject. If genius is 'the capacity to take infinite pains,' Virchow is an example, as indeed he is of genius however defined.

"Virchow has always emphasized and in his work exemplified the fact that it is method and not doctrine which characterized his school, if I may be permitted to use in a good sense a term which has such a baneful sound in the history of medicine. He says in his interesting article on 'The Scientific Method and Points of View in Therapeutics'; 'The Method of Investigation is That Which is Essential and Determining. It is the method which distinguishes the Harveys, the Hallers, the Bells, the Magendies, and the Müllers from their smaller contemporaries. This is the soul of the natural sciences.' Virchow's method is none other than that which alone is productive of results in natural science—the familiar and long-tried, but in medicine often enough neglected, method of careful, accurate observation, properly directed experimentation, and deduction of general principles based upon sound reasoning and full knowledge.

"The true position belonging to pathological anatomy was first clearly defined by Virchow. His convincing critique of Rokitansky's general pathology was directed as he said, 'not against the Rokitansky whose special pathological anatomy remains untouched, but against the Rokitansky who had reached out beyond the boundaries of pathological anatomy.' Virchow recognized promptly the error of his predecessors in attempting to construct a general pathology, or physiological pathology, as he prefers to call it, solely from the observation of morbid changes at the autopsy table. He pointed out the harm which had been done to practical medicine by such mistaken attempts. General pathology must call to its service not only morbid anatomy, but also experiment and clinical medicine. Nor is practical medicine to be founded upon pathological anatomy and general pathology alone, important as these are to the physician in many ways. Clinical medicine, as well as every other department of medicine, must be investigated by itself, deriving, as should every science, all the aid it can from allied sciences.

"Virchow broke completely with the old ontological view that disease is something apart, an entity. He promulgated the conception that disease is life under changed conditions, and that its operations are subject to the same laws as control the workings of the body in health. Hence the fundamental importance of a knowledge of physiology to the pathologist and the physician.

"The far-reaching import of this conception of disease was never more apparent than since the discovery of the relation of micro-organisms to the causation of infectious diseases, and here I may be permitted a word as to Virchow's attitude toward this great discovery. It is unquestionably a mistake to suppose that it is not a sympathetic one, for the reason that various matters pertaining to the subject have encountered his criticism.

"Virchow, as Dr. Osler has just told us, is himself a pioneer in the field of preventive medicine, as is well known to all acquainted with his investigations, at the outset of his career, of famine typhus in Upper Silesia, and with his other contributions in this domain. One must know something of the political conditions in Prussia in those days to appreciate fully the courage of this young physician of 26 in pointing out the dreadful social conditions in which the people of this region, ravaged by typhus, were living and the duty of the State to intervene by appropriate sanitary improvements! This work was eventually instrumental in introducing a new era of sanitary reform in Germany. Virchow's special investigations relating to infection and parasitic diseases entitle him to a prominent place in the history of this important chapter in Pathology. I need only call to mind his studies on trichinosis.

"But Virchow has done an important service in defending the fundamental principles of cellular pathology and in sustaining the conception of disease to which I have referred, by making it clear that the parasite is not the disease, that it is the disturbances of cellular structure and function induced directly or indirectly by the parasite which constitute the essence of the disease, and that new properties acquired by the fluids of the body through the action of bacteria, which seemed to be leading some short-sighted observers back to the old humoralism, must in the last analysis be derived from the cells. Cellular pathology has only been strengthened by the great discoveries in bacteriology, and ontological and humoral conceptions of disease have been revived in these later days only to be discarded by all profound thinkers in pathology. Virchow's critical attitude toward hasty conclusions and generalizations in this new branch of science has really been of great service.

"I have left myself no time to speak of Virchow as a teacher of pathology, or as the organizer of a great laboratory, the first devoted to the subject and the Mecca for students from all countries who are proud to call him their master.

"Fifty years ago Rudolf Virchow stood in the center of the world of scientific medicine; to-day at the completion of his eightieth year, still energetic and active, he stands in the same place. His fame is imperishable. His name will remain for all time one of the glories of medicine and science. May the years which remain to him be full of health, and happiness and prosperity!"

Personal Reminiscences.—Dr. Andrew H. Smith of New York then spoke of Virchow as a man and as a teacher and in a very charming manner took his hearers back to the old Pathological Institute of Berlin; in 1858-1859 Virchow was then thirty-eight years of age and was full of enthusiasm and ingenious devices

for teaching of pathological anatomy. He told how the early autopsies had been performed and spoke of his surprise and delight to see how Virchow revolutionized for him and his students the early ideas of the functions of an autopsy. Previously such examinations had been made simply to try to ascertain what the man had died of and the examinations were very superficial; small openings being practised and minute dissections alone of the affected organs made. Virchow changed all this; with one fell swoop, he would open the body from the chin to the pubes and then would follow his classical method of opening the chest. Dead men literally spoke while Virchow performed an autopsy and the idea was "how much can be learned about this body from all possible points of view." The cause of death was but a secondary consideration. The dead body was a mine to be explored and made to yield rich products of information.

He also spoke of the methods for teaching microscopical pathology as then carried on, telling in detail of the railroad of microscopes that Virchow had constructed in his laboratory.

Dr. Smith spoke of having commenced to translate the "Cellular Pathology" and of his trouble in finding a publisher, revealing incidentally that publishers at that day were as shortsighted in not recognizing the work of genius as at the present time and that then as well as now commercial points of view seemed to be in the ascendancy.

In the matter of style, Dr. Smith said that Virchow had complained bitterly of the vernicular form of medical literature in vogue in his youth and he at that time commenced to put his thought in simple and straightforward literary form. A style which was marvellously clear and clean cut. Virchow was most democratic as a man and most approachable. He was always ready to help his students and was a man of most charming and engaging personality.

Virchow as a Citizen.—Dr. A. Jacobi of New York gave a stirring address which was greatly enjoyed by all those present. He said:

RUDOLF LUDWIG KARL VIRCHOW was born October 13, 1821, at Schivelbein in Pomerania, was educated from 1835 at the Gymnasium of Cöslin, went after his examination for "maturity" to the medical Frederic William Institute at Berlin—the school for military surgeons—graduated in 1843; became prosector in the Charité Hospital 1846, gave courses in pathological anatomy; obtained the permission to deliver lectures in the University of Berlin, as Privat docent, 1847; was sent February 20, 1848, as medical expert to Upper Silesia to study the "hunger typhus" epidemic; returned to Berlin March 20th and delivered his report; was on account of it deprived of his governmental positions; reinstated in part only on account of the urgent petitions of a large part of the profession of Berlin, but remained then and for a long time in the honorable possession of the hatred aroused in the governmental party by his independent bearing, and his zeal in asking for reforms, and left Berlin to assume the offered professorship of pathological anatomy at Würzburg, to the great relief of the Prussian government.

This is how it all happened. When his communications on the Silesian epidemic of the starvation typhus were published, they were found to contain much more than the government relished. They were medical; there were histories of cases and autopsies; they were also historical, scientific, hygienic and reformatory. He described graphically and truthfully the revolting neglect through centuries of the Polish population of Upper Silesia, their poverty, dirtiness, ignorance and brutality, their mental slavery under the Catholic hierarchy, and their physical abjectness under the Prussian bureauracy and feudalism. He looked for salvation not in medication, but in education, in social reforms, in culture with its daughters: liberty and welfare, in full and unfettered Democracy; education of the people, agricultural institutes, raising and instructing the numerous orphans; road building and general recognition of the fact that, as he expressed it, "with our century begins the social era." A few weeks after he edited with Leubuscher, a new magazine, the *Medical Reform.* In the first essay he pronounced the doctrine, that "the physicians are the natural attorneys of the poor, and the social problem belongs in its intrinsic parts to their jurisdiction." Then he urged a reform of the public relief of the sick which he declared must be obligatory; and the recognition of the need of a hygienic existence of every human being; reforms in the medical profession, in University education, and in the entire medical legislation. Do not forget that all this happened and was preached just before and immediately after the March revolution of 1848. Remembering that, you will comprehend why the Prussian Government dismissed him, again reëstablished him in a part of his positions, unwillingly but under the pressure exercised by the profession of Berlin. For it was the time when the Prussian government, in spite of its temporary defeat, had retained all its absolutistic instincts, had exhibited all its cowardice common to all tyrants, and its senseless confusion during unexpected difficulties, its revengeful reactionary cruelty after unheard of humiliation—indeed, on March 19th his Majesty was compelled by the victorious people to uncover his Royal head in the presence of his dead enemies shot on the barricades of the day before. Thus it happened that when the call to Würzburg reached Virchow, he was encouraged by the grinning authorities to accept it. In the very last numbers of his *Medical Reform* he said: "The med-

ical reform we had in mind, was a reform of science and society in general." Now you will also comprehend that among the revolutionary youth that died on the battle-fields or pined in dungeons, not a few were students of medicine.

Such a man never lost his interest in public affairs, and never gave up his labors in their behalf. The public hygiene of his country, of all countries, owes much to his study and initiative. He was the main factor in the great work of canalization of Berlin, the cultivation of vast territories by the utilization of sewage, the organization of medical care of the sick, the erection of hospitals such as Moabit, Friedrichshayn, Urban, Empress Frederic Child's Hospital, Dalldorf, Lichtenberg. The problems of tenements, of child and general mortality have forever occupied him. Nobody more than Virchow has taught the medical world the importance of medical statistics; nobody before him, or like him, has utilized physical statistics more uniformly and more successfully in the domains of anthropology and ethnology, and thus co-ordinated—under the influence of the same methods—all the branches of biological research.

The organization of the medical care of the soldiers during the campaigns of 1866 and 1870 was partly his work. The history of hospitals and hospital work was his study for years. It was then that he wrote what I had the proud gladness of quoting twenty years ago in regard to our doings on this side of the Atlantic: "The French army lost, in the Crimean War, thirty-three per cent. of its men, viz., 95,615. Of this number, 10,240 were killed on the battlefields, and about as many died of their wounds in the hospitals. More than 75,000 men died of infectious diseases. In the American Civil War 97,000 died of their wounds, and 184,000 perished of infectious and other diseases. What a vast amount of pain and misery! What an ocean of blood and tears! And besides, what a number of errors, mistakes and prejudices! It is not necessary to enumerate the long list of blunders and sins. They are so well known as to serve in the future as warning examples. Let me say here that it was not misfortune alone that showed where the cause of the evil was, and then provided aid. If the French learned little or nothing in the Crimea, and the Americans so much in their Civil War as to create a new era in military medicine, the explanation is not to be sought for in the immensity of misfortune and misery undergone by the Americans, for they did not suffer any more than the French did in the Crimea. The explanation is in the critical and thoroughly scientific spirit, the clear perception, the sound and practical common sense which penetrated gradually every part of the American military administration, and which, with the astounding coöperation of an entire nation, accomplished more humane results than any great war ever produced before. Whoever studies the copious publications of the medical staff of the American army, must again and again be astonished at the vast experience collected in them. Absolute accuracy of details, the most painstaking statistics, acquaintance with all branches of medical learning, and a comprehensive style, are united in them for the purpose of collecting and preserving, in the interest of the present and future generations, the new knowledge so dearly bought."

That is how a great writer expressed his knowledge, and a man fond of democratic government his sympathy with the results of the spontaneous work of a republican commonwealth. His interest in the welfare of the people he proved through many years by his participation in societies made up of the public at large; he lectured there frequently, mostly on physiological topics, and for dozens of years he has found the time to edit with Holtzendorff, an immense collection of popular lectures contributed by special workers all over the land.

For nearly forty years he had a seat in the town council of Berlin. It was through his influence mostly, that Berlin with its more than two millions of inhabitants, is a clean, healthy, well governed city, well governed in spite of the constant interference by the political government of the country. Indeed I do not know of any large city that has for dozens of years understood so well the municipal interests of the people as differentiated from the political demands of the Empire.

Only yesterday the word was passed in the Council of Berlin that the encroachments of the government ought not be endured. Dozens of years he was a member of the representative council of Prussia, and of the parliament of the Empire. That he selected his seat on the benches of the opposition is self-understood. When he was young he was known to be a revolutionist. He was maltreated by the government to the full extent of its possibilities; fortunately for him, and for all of us, he was not caught on a field of battle or in a conspiracy, actual or alleged, that could land him behind prison bars; but his tendencies were well understood. When once he demonstrated his new discoveries of thrombi and embolism in a case of pulmonary obstruction, old Schönlein, who was watching the result of his clinical activity in the morgue, shrugged his shoulders and said: "I notice you see barricades everywhere." This barricader now raised barricades indeed against many a nefarious project in Parliament. Not only did he discuss questions of hygiene and education in which his authority was readily acknowledged, but he was always alert and effective in the treatment of political questions of every kind. The chancellor who never cared for principle or right, but for opportunity and might only, found in

Virchow a lively critic and a frequent obstacle. There was a time when the great Bismarck challenged Virchow to fight a duel with him. The greater Virchow declined the honor of making a brute of himself, or of being made a corpse of by the vandal of blood and iron. His main adversary indeed was this man Bismarck who through thirty years of oppressive measures, dissolution of Parliaments, governing without the assent of the representatives of the people, sudden changes both of economical and ecclesiastical policy and party affiliations, brutal assaults on the rights of individuals, the freedom of the press, and the principles of the constitution that was purchased with the blood of the best part of the nation—though he succeeded in throwing into the lap of the Hohenzollern family additional large territories, and in obtaining for Germany a partial unity instead of the complete integrity we were fighting and conspiring for when we were young, has done more than any German in history to emasculate German politics and demoralize the public conscience.

Virchow, on the contrary, resisted to the utmost the lawlessness of absolutism, claimed that law should be supreme, the rights of citizens respected, the office holders know and live up to their duties, the constitution be carefully guarded and protected, and peace not rendered more expensive and exhausting than even war, through military expenses and pensions without limit, and the withdrawal of profitable labor, and enforced idleness of a million of men.

While engaged in scientific research which in universality, novelty and reforming power, are surpassed or equaled by none that are immortalized in the history of medicine, Virchow never ceased to feel that he did not only belong to theoretical and practical science, but to his people; and moreover, while his theoretical work has always a practical bearing and result, so his political and social views have a practical tendency.

He was born one of the people, and remained a friend of the people. He need not turn politician, he was and is politician born. We in this our country are in frequent danger of forgetting that at one time at least, the most intelligent, wise and pure men of this nation were our foremost politicians. Without the controlling sympathy of the very best, the Constitution of the United States would not have seen the light. We have since descended sometimes, aye many times, to the fear that only a second-rate intellect and a third-rate morality make a successful and zealous politician, losing sight of the fact that Aristotle already defined man as a "political being" and insisted upon the labor of all in the interest of all.

Virchow's example should teach, particularly young medical men, that thorough science and good citizenship do not exclude each other. Indeed there is nobody so removed from the midst of his fellows, so absorbed in abstract studies, that has no interests in common with the rest of mankind. To prove your sympathy, what you have to spend in time, in activity, in money, should be given to the cause of the people, in the town and in the country, and particularly in critical periods of our history, like that of to-day.

The parliamentary labor performed by Virchow would easily have taken the whole time and all the efforts of a vigorous man of intellect. What was it to him who bears his eighty years lightly and has a right to ask for many more? In the preface of his "Morbid Tumors" he says his political work was his recreation from labors more fatiguing and onerous.

His labors have been many like his honors that have been many. He has stood them all. His labors he sought, his honors came to him unsought.

There was a time when the powers politic would have been glad to destroy or to cripple him. When he proved the man of the century and the star to which thousands liked to hitch their cars, he became an unapproachable power himself. He became so big that they forgave him. Then titles would come, and places on government boards, and decorations enough to cover the liveries of a Chatham Street store. But more came to him.

There is no scientific body, medical, anthropological, ethnological, that does not feel honored by his accepting a place on its roll of honorary membership; no congress at which he is not the most honored guest; no book on any medical or anthropological topic in which he is not quoted as the main authority. And still more is due him. The history of the City of Berlin, beautiful, healthy, hygienic, could never be written without his name on every page; the history of Prussian and German politics will not be complete without it. The place of honor belongs to him, and to his friends who fought with him, and for the people. His place in science is secure, and his good citizenship will never be doubted.

His life is a great lesson to all. I see men of international fame here, of genius, covered with glory and loved and admired by all. But there is nobody who claims to equal him, or to do more than to imitate him. Now the lesson we should learn, do learn, from his example, is that no matter how high your position, how extensive your learning, how numerous your adoring pupils, you hail from the people, are one of them, part of human society, with duties of reciprocity and good citizenship. The lessons hundreds of my New York City friends should learn from what is going on this evening, is also this, that we in this town, of which we are apt to say we are so proud, and which we should teach to be proud of us, its sons and citizens, that we should learn from the presence of so many of the distinguished

men of Baltimore, Philadelphia, and Boston—as busy as any of us and as necessary to the welfare of the people—how to sacrifice an hour or a day for a demonstration as sacred as this of to-night, that is taking place in New York, in Berlin, and many other centers of science and good citizenship. Never, never was there a more urgent call on the profession and a more appropriate opportunity for an enthusiastic meeting than this anniversary of this octogenarian, greatest in science and great in citizenship. It should not be said that Boston has Bunker Hill and Harvard, Philadelphia, Federal Hall and the oldest Medical School, Baltimore has Johns Hopkins, and we should not told that New York has nothing but Wall Street and its spirit. Now, we, of this City, thank those who have come from afar to adorn this occasion by their presence and their famous names, for being with us. A similar opportunity may never arise for any of us. For history does not easily repeat itself, and the particularly grand blending of great qualities with immense powers is no creature of every decade or even every country. What Virchow was, what he is, will always be appreciated and honored. There is no ephemeral fiber in his existence. One thing we can say of him with Goethe: "He has satisfied the best of his era, he has lived for all time."

Wer hat den Besten seiner Zeit genug gethan,
Der hat gelebt für alle Zeiten.

REPORT OF THE SUMMER WORK OF THE MILK COMMISSION OF THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

BY HENRY DWIGHT CHAPIN, M.D.,
OF NEW YORK;
CHAIRMAN OF THE COMMISSION.

It may be of interest to the members of the Society to briefly rehearse the incidents leading up to the formation of a Milk Commission, before speaking of its work. A year and a half ago an evening was devoted to a discussion of the milk problem, especially in connection with large cities. A number of experts were present, including the Chief of the Dairy Division of the U. S. Department of Agriculture. The subject seemed one of such importance and aroused so much interest that the Society determined to form a commission that should study the best methods of improving the milk supply of New York. The time seemed ripe for such a movement, as the interest aroused and the success of the work have since proven. Moreover, the Medical Society of the County of New York, as the public and legal representative of the medical profession, and the guardian of the City's health, seemed the proper body to undertake such a work.

The first meeting of the Commission was devoted to a discussion of the problem and how it might best be approached. The milk that is put into a large city must be gathered from diverse and distant sources, transported many miles, and finally distributed after many vicissitudes and changes to the customer, who himself keeps it a certain length of time, possibly under unfavorable conditions, before its use. When we consider that all this happens to a vital fluid that is unstable in its composition, that is sensitive to many unavoidable factors, such as temperature, atmospheric effects, shaking, and, above all, to dirt and dirty utensils, the complexity of the question may be appreciated. Heretofore most of the work done in a public study of a city's milk supply, has concerned itself principally with the chemical ingredients of milk, more particularly the amount of butter fat it contains.

One of the members of the Commission, having studied this subject for several years, found that the milk of New York, especially as supplied by the best dealers, runs fairly high in butter fat. While the law requires 3 per cent., an examination of over twenty samples from diverse sources showed an average of about 4 per cent. to be present, and not infrequently 5 per cent. is reached by the best dairies. Further examination showed that much was to be desired in point of cleanliness of the milk. Milk is an exceedingly good culture medium for the growth of bacteria of all kinds, and modern studies show that the presence and numbers of bacteria form a good gauge of the general condition of the milk, and the care with which it has been handled. The proper preservation of milk is also involved, as it is well known that the deterioration of milk from acid changes is due to bacterial growth. Ordinary bacteria that contaminate and grow luxuriously in milk come from the dirt that follows a careless handling of the milk, anywhere from its first production to its delivery.

It seemed well to the Commission to establish an advanced standard of clean milk for the ordinary dealer, and the index of cleanliness would be established by a bacterial count. In other words, a bacterial standard would be applied as a gauge of the condition of milk. As this work was to be entirely voluntary, as far as the dealers were concerned, it was decided to invite them to a conference with the Commission, and learn their ideas as to the feasibility of the undertaking. Accordingly, 180 invitations were sent out to dealers in Manhattan and the Bronx, this including all those of any financial importance, as shown by their commercial ratings. The meeting was held on November 16th, at the Academy of Medicine and about 50 dealers were present. They were invited to give their views freely as to whether part of their milk could not be put out according to an advanced standard for the benefit of infants, invalids, or any who desired a superior article. While many practical difficulties were urged, the general sense of the meeting seemed to be that with some extra care and expense many improvements could be made,

under proper guidance, in putting out a strictly clean milk. Encouraged by this expression of opinion, as well as by the good will and spirit shown by the dealers, the Commission determined to call a second meeting of those who were willing to have their milk examined and certified by the Commission. In the meantime, a series of suggestions, adapted from the dairy rules of the United States Department of Agriculture, were combined in a circular, together with a tentative standard adopted by the Commission. The final paragraph explains the latter as follows:

"The Milk Commission of the New York County Medical Society agrees to guarantee or certify the milk of all dealers desiring such certificate. A special label will be furnished for this purpose. The standard required to obtain this indorsement will be that the acidity must not be higher than 2 per cent., and that the milk must not contain more than 30,000 germs, or bacteria of any kind, to the cubic centimeter. This will be tentatively adopted as a standard of clean milk, as bacteria get into the milk through lack of cleanliness during the milking and careless handling of the milk after the milking, and hence is a good clue to the care bestowed in the production and general handling of milk. The milk, before testing, must be in its natural state, not having been heated and without the addition of coloring matter or preservatives. The butter fat must reach 3.5 per cent. Examination must be made by the experts retained by the Commission, with a frequency at their option, according to the season and the general condition of the milk under inspection, and at least once a month. The Commission reserves the right to change its standard, in any reasonable manner, upon due notice being given to the dealer. The expense of the examination will be met by the dealer. All reports of examinations will be strictly confidential between the Commission and the individual dealer."

About fifteen dealers attended the second meeting, which was understood to include all who were at that time willing to work with the Commission. A report was then made to the Comitia Minora, who authorized the continuance of the work along these lines.

The first examination was made March 4th, for certification, the count showing 58,500, with butter fat 3 per cent. It may be of interest here to see how the better grades of milk in New York run in bacteria. The following tests, furnished by Dr. Park, will show the amount of bacterial contamination of milk put into New York, during a winter and summer day. The first was taken November 19, 1900, being a mild winter day; temperature during the afternoon was 70 and at night 50° F. Samples of milk taken from carts, received directly from cars, gave an average temperature of about 52° F., the range being from 50 to 58° F. The number in the six samples ran as follows: 56,000; 128,000; 35,000; 256,000; 13,600; 2,880,000. For a summer day, June 29, 1901, was taken, the day temperature being 90° F. and the night temperature 78° F. Six samples taken at random show as follows: 520,000; 30,000,000; 3,530,000; 12,000,000; 216,000,000; 9,600,000.

Some idea of the extent of the bacteriological work upon milk done for the Commission, will be appreciated by stating that from March 4th to the present date, 800 separate bacteriological examinations have been made. This laborious undertaking has been accomplished by Dr. Sarah Belcher, to whose zeal and enthusiasm much of the success of the work is due. The mission is also greatly indebted to Dr. Park for valuable oversight and advice, and to the Rockefeller Institute for Medical Research for its cooperation in allowing Dr. Belcher to render these services as part of the work of the Institute. Bacterial tests have been made in the Research Laboratory of the Department of Health. After visits to a number of farms and dairies, it was aimed to classify the various sources of contamination, so that each one might be separately inspected and eliminated as the source of trouble, or corrected, if found at fault. In order to reduce to practical results these bacterial researches, the following factors were considered and carefully studied:

1. Conditions of barn.
2. Condition of cows.
3. The milkers.
4. Condition of utensils.
5. Processes of cooling.
6. Transportation.
7. Condition of cans or bottles when returned from city.

1. *Conditions of Barn.*—Dirt and dust, usually so abundant in an average barn, readily get into the stream of milk or pail and form a fruitful source of bacterial contamination. The common sources of dust are the hay-loft overhead, cobwebs on walls and ceiling, loose boards, dirty windows, floors of dirt, unclean manure gutters, excessive bedding, storage of grain or feed in the barn, the rations, such as piles of hay placed near the milking and the storage of farm or other utensils in the barn, that soon become covered with dust. A dirty barn quickly raises the bacteria in milk there collected. Thus, on June 8th a cow was milked in such a barn and an examination of the milk showed 120,000 bacteria to each cubic centimeter. At the same day and hour, another cow, in apparently the same condition, was milked in the adjoining pasture, away from the dust of the barn, the milk here showing only 26,000. This experiment repeated twenty times in various localities, always gave similar results. There is invariably a large increase of bacteria in milk collected in a dirty barn. Even when a barn has been cleaned up, some source of dust may be overlooked and cause trouble. Thus, on June 15th, the premises as well as the cows were examined after the barn had been cleaned. Twelve cows standing in a row in the barn all showed a low bacterial count in the milk separately examined, except the one at the end, which showed 1,000,000. This cow stood next to a pile of dry feed, which was the only factor to account for the contamination. Here was explained an aberration in the milk of this barn that we could not at first understand, as everything had been cleaned according to directions, but this little detail overlooked. Many visits and experiments have thus shown that con-

tamination can easily be avoided if the source is discovered.

2. *Condition of Cow.*—Much dirt that gets into milk comes directly from the cow. When the cow is being milked the udder is pulled down, which loosens dandruff, hairs and dirt from all the adjacent parts. Particular sources of impurity that are apt to be overlooked in cleaning a cow are the folds between the udder and the flanks and dirt on the tail. Fifty bacterial tests were made in direct relation to the cow. The following, in which clean barns and milkers figured in connection with dirty cows, will serve as an example. Four dirty cows under above conditions gave an average count of 90,000. Four other cows from the same herd in the same barn, were carefully cleaned and then milked by the same man and gave an average count of only 2,000.

3. *The Milker.*—A fruitful source of dirt is directly attributed to the milker. The dirt may come from the hair, hands, especially when chapped and scaly, fingernails, tobacco or clothing. It was found that the milk from certain men always gave a high bacterial count that could invariably be traced to some of the aforementioned sources. It is better to have the milkers clean-shaven, and, when milking, they should be clad in white duck suits or blue overalls that are frequently washed. Young, single men make the best milkers, as they are less apt than married men to carry infection from the home. The details of their living admit of better oversight.

4. *The Utensils.*—These include pails, strainers, condition of creamery or dairy room, aerators, stationary vats, portable vats, and bottles or cans. It is sometimes difficult to find which of these factors is at fault, but the condition of the pail or strainer is very important, as when they were found at all dirty the bacterial count was always high. Thus, in a case where an ordinary pail and strainer was used the count was 80,000. On the same day, from the same barn and cows, a sterilized pail and strainer being substituted, the count dropped to 5,000. All utensils must be strictly clean, and, if possible, steamed or sterilized. It was found that cleanliness depended both upon apparatus and proper methods of cleaning. (1) In every utensil all seams must be well soldered to avoid hiding-places for traces of dirt and coagulated milk. (2) Cold or lukewarm water must first be used to avoid coagulation of particles of milk, then a cleansing with hot water, with soap or soda, and a final rinsing with hot water. After washing, cans or bottles should be turned bottom up on racks, and, if possible, steamed or sterilized. The following interesting experiment was made: Two samples were taken from the same can of milk—one from the top, showing a count of 5,000, while the one from the bottom gave 80,000. As the can had been standing in ice the lower part was cooler. The milk had also been strained and creaming had not taken place, hence the conclusion was that the bottom of the can was not clean, and had contaminated the milk near at hand. On the whole, it was found that the simpler the pail the better; one that can be milked into quickly and cleaned easily is the best. The plain open pail gave the best results. It was found that metal strainers attached to pails were undesirable owing to difficulty in keeping them clean. Particles of dirt that might be removed later by straining are broken up by the force of the stream of milk and thus disseminated through the milk. Thus, samples from pails having strainers uniformly gave a higher bacterial count than when strainers were not used, other conditions being as nearly as possible the same. The best general strainers are absorbent cotton, cheese-cloth or Turkish toweling attached to the receiving-cans by clothes-pins. If a metal strainer is then used, it should be as simple as possible, and the wire mesh must be carefully cleaned with a stiff brush. If an aerator or vats of any kind are used, they must be cleaned and, when possible, steamed or sterilized. All joints and seams must be smooth and the faucets and pipes likewise frequently steamed or sterilized. By requiring more apparatus to be kept clean, aeration, as ordinarily practised, increases the danger of bacterial contamination. The following experiment was made on July 22d: It was found that samples of milk from pail and strainer on a certain farm averaged 3,000. After aeration by the farmer, according to his usual method, the samples gave a bacterial count of 1,404,000. Here a man with clean cows, barns and milkers, was contaminating the milk by faulty utensils. In the hands of men understanding the importance of strict cleanliness, the aerators are not a source of danger, but if the aerator is not strictly clean and in proper surroundings, the ordinary farmer may lose more than he gains by its use. Dirty ice, flies, floating dust, pipes and faucets are sources of bacterial contamination. It has been found that with a clean barn, clean cow and clean milker, the ordinary so-called "cow odor" is not present.

5. *Processes of Cooling.*—This we have found to be one of the most important factors in the production of uncontaminated milk. The whole future condition of the milk depends a good deal upon its handling during the first forty-five minutes. The sooner it is brought to a temperature at or below 45° F., at which point the growth of bacteria is greatly inhibited, the better. Many inspections of premises that were clean enough to produce a clean milk gave disappointing results when the milk was allowed to stand for more than an hour without being cooled. Where the milk was brought below 45° F. within twenty or thirty minutes, a low bacterial count *always* resulted, other conditions being right. In an experiment made July 25th, tests were made of milk collected from clean cows in a clean barn, the average count from the pail being 7,000. It was then cooled not lower than 60° F., by a slow process, and after two hours it was still standing

at 60° F., when a bacterial count gave 89,000. Five days later, the milk under apparently similar conditions was cooled down to 45° F. within ten minutes from milking, and then showed a count of only 12,000. This experiment has been repeated at six different farms, in various localities, with similar results. We have found the temperature of springs during the summer to vary from 45° to 70° F., with an average of about 55° F. Hence this method of cooling is uncertain and defective unless ice is added to the spring. Ice is always necessary to the farmer who is handling milk. When springs are used, the surroundings must be kept clean and the water uncontaminated at its source.

6. *Transportation.*—As soon as the milk is put into bottles or cans it must at once be surrounded by ice. If they are kept standing in a vat, the temperature of the water must be at least 40° F., as the milk will then be a few degrees higher. This temperature must be maintained by ice until the car is reached, if the milk is in bottles; if in cans, by means of jackets. The ordinary freight car should not be used. We have found that refrigerator cars, with doors at the end kept closed, are necessary. The cars should be loaded and unloaded from the center. The railroads can coöperate in this important work by supplying refrigerator cars and ice. When the dealer removes the milk from the car, it should be re-iced on the platform or at the depot and kept iced until delivered.

7. *Condition of Bottles When Returned.*—Much contamination can be avoided if the consumer would properly cleanse the bottles before returning them. They should be washed promptly, and never used for any other purpose. We have found cases where drugs, dirt, and even urine, have been found in them. In houses in which there are contagious diseases, no bottles should be returned, but broken and thrown away. In apartment houses, it is usually customary to collect the bottles in the basement, where they are afterward sorted out by the dealers. All kinds of impurity thus get in, making it frequently impossible to thoroughly cleanse these bottles. Thousands of bottles every year are collected by Italians from the dumps, and returned to the Bottle Association, which sorts them out, washes, and returns them to the owners.

In our inspection of creameries, it was found that thousands of Croton bugs were returned in bottles and boxes. The cans are also often returned with portions of decomposing milk remaining in them, the boxes containing the bottles may be mouldy, with parts of the wood rotten from being smeared with decomposing milk, and so forth. The railroads should be requested never to receive bottles, boxes or cans containing any fluid milk. We found that boxes and cans are often thrown off from the train by the roadside, where they may be left for hours, exposed to the sun. Utensils subjected to this treatment are only fit to be used again after sterilization, and farmers usually have no such facilities; the creameries may have, but seldom use them.

The various data here recounted are the results of a summer study of the milk question. The information is the result of thirty visits made to various farms and dairies, some at a distance of 180 miles. Each of these visits consumed, at least, one day and some several days, so that a thorough study of the matter could be made. In the work of the Commission, the individual farm or dairy, and not the milk company, has been regarded as the unit for study and investigation. It was found necessary to work in this manner in order to get good results; in some cases, several visits were made to a given plant. As an example, a large plant was visited on August 11th; the farm was visited during milking time. The notes show that the cows were fairly clean, the barn was defective, showing hay protruding from the ceiling and covered with cobwebs and dirt. Windows dirty. The barn had a southern exposure, so that the sun increased the heat. The manure gutter was not clean; the bedding of shavings had not been removed. Various articles were stored in the barn, such as feed, farming utensils, and the clothing of the men. The cows were getting full rations of hay; the animals were hot and restless, and covered with flies, which necessitated a constant moving of the tail. No means were supplied for keeping the cow quiet during milking. The milk was strained in the barn with a wire strainer, which was bent and rusty. The dairy-room was hot and sunny, showing dust and flies. The milk was passed over an aerator, in which the temperature of the water was found to be 60° F.; the receiving vat and stationary vats were not covered, so that flies and dirt got in. The bottles were standing in ice-water at 50° F. A fair sample of milk produced under these conditions and tested at once, showed a bacterial count of 455,000.

Suggestions just described were offered, and four days later a second visit was made. As the result of specific directions, in the barn the walls were whitewashed, windows cleaned, and green shades had been placed at the windows having a southern exposure. The floor was cleaned and the bedding had been removed; the manure gutter was also clean, and land plaster had been sprinkled on the floor and manure gutter. All storage of feed and utensils had been removed. The cows were getting scant grain rations, so that there was not a large pile of hay before the animal that would fill the air with dust and induce movements of the body. The cows were well cleaned. The barn was cooler, and hence the animals were not so restless. The milk was not strained in the barn, but removed at once to the dairy. The dairy-room was clean, dark and cool, with receiving and stationary vats covered with cheese-cloth. The temperature of the water in the aerator was 40° F. The bottles were standing in ice-water at 38° F. A fair sample of milk thus produced, showed a count of only

3,600 to the cubic centimeter. This is not an exceptional condition, as a similar experience was repeated at four different times and places. This shows that an elaborate and expensive plant is not necessary to put out a clean milk. What is needed is intelligent attention to detail. A small as well as a large producer can furnish clean milk.

The following example will illustrate an experience with a small dealer, the visit being made September 5th. The cows, barn and man fairly clean. Utensils fair. No aerator and no steam. Ice was being used sparingly. Milk drawn under these conditions was placed in water at 70° F., then taken to the creamery for bottling and sent to the city. An examination here showed a count of 89,000. Various suggestions were offered, and the second visit made in eight days. Result, cows and barn well cleaned, the milk strained through absorbent cotton and cheese-cloth attached by clothes-pins to a forty-quart can, which was kept standing in a box surrounded by ice. This can had previously been steamed for twenty minutes at the creamery. The can was then taken to the creamery and placed in a vat of ice-water at a temperature of 40° F. In three hours the temperature of the milk stood at 44° F. It was then bottled and sent to the city. A sample of this milk showed a count of 5,400, as the result of the few simple changes suggested. Even a creamery is not necessary for a small dealer to put out milk up to the standard of the Commission. As an example, milk was sent from a small farmer, where cooling to 40° F. was practised within fifteen minutes after milking. This milk was sent to the city in 40-quart cans, surrounded by jackets. Samples taken on the platform in New York at 3 a. m. showed a count of only 3,000.

All the visits made to these farms were educational. The whole family, including wife and children, became interested and coöperated in the work. The attention of neighbors was also attracted to the improvements, which were often imitated, and formed the subject of evening discussion at the village grocery-store.

The Commission has no special method to advise, but asks a hearty coöperation from everyone concerned in handling the milk. The methods must vary with each plant. In general, it may be said that the following three heads include the essential conditions: (1) Strict cleanliness, which includes the barns, yards, cows, milkers and all utensils. Bacteria which get into the milk by means of dirt are thus thoroughly excluded; (2) rapid and sufficient cooling of the milk (the few bacteria that do get in are thus prevented from growing); (3) thorough icing around the milk until it reaches the consumer. The production of toxins from the growth of bacteria is thus retarded.

In every case the dealer has been able to reach the standard of the Commission without expensive apparatus, by following the indicated details. The one thing always necessary is plenty of ice. At the same time, great labor has been done by farmers and dairymen as the result of suggestions by the Commission. New plumbing has been put in, new dairy-rooms have been built, floors have been cemented, ceilings made tight, and time and endeavor have not been spared. One dealer was so impressed with the subject of right conditions that a special new barn was put up in order to meet them. Two others are planning new barns that will ensure hygienic conditions. Even where the milk has not reached the standard for certifying, great advances have been made, and the general output improved. Eight dealers are now putting out some of their milk up to the standard of the Commission. They are as follows: Slawson Bros., Briar Cliff Farm, T. W. Decker & Sons, Mrs. Van Zandt, Sheffield Farms, Mr. Tuthill, Harlem, Century Co., Locust Farms, and Mr. Keller. Many others are making changes and applying for a certification, who will doubtless pass the test of the Commission.

In spite of the summer having been the hottest in thirty-one years, all those who have been certified have kept up to the standard under most trying conditions. The thanks of the Commission and of the community at large, are due to these dealers, who have shown great interest in this work and have not spared labor or sacrifice in keeping up to the standard. The milk of each dealer has been examined about twice a month during the summer, and labels given that can be placed in the mouth of the bottle, as a proof of certification. The bottle for examination is collected from the dealer in the morning, placed in a bag surrounded by ice, and at once taken to the laboratory. If the milk shows a test close to the limit established by the Commission, a second examination is made in a few days. In the meantime, an effort is made to find out the source of trouble, in order that it may be corrected.

The Commission feel gratified at the interest excited in this movement on the part of the farmers, milk-dealers, the daily press, and the dairy journals. It is hoped by this movement to inaugurate a general improvement in the production and handling of milk destined for large cities.

Virchow Celebration in Chicago.—The German-American Medical Society celebrated the eightieth birthday of Professor Virchow in the new banquet hall of the Bismarck October 12th. Seventy physicians sat down to the feast. Dr. Gustav Fuetterer acted as toastmaster. The committee was composed of Dr. Saurenhaus, Dr. Heyn, and Dr. Gustav Kollischer. Dr. G. Frank Lydston and Dr. Norval H. Pierce, guests of the Society, made speeches.

MEDICAL PROGRESS.

Diseases of the Esophagus and Esophagoscopy.— The possibility of examining the esophagus visually throughout its entire length makes it comparatively easy to distinguish anatomical alterations from nervous and neuromuscular conditions, nevertheless esophagoscopy is rarely utilized to-day, even by specialists, because of its supposed difficulties and dangers. The technic of this procedure is fully described by F. SCHILLING (*Wiener med. Bl.*, Sept. 5, 1901). Ordinarily the esophageal mucous membrane appears pale; in inflammatory conditions it is red and its blood-vessels are visible. Stricture is due to compression from without, or to tumors, infiltrations or scars developing in or springing from a wall of the canal. Cicatricial contraction is usually a slow process, even when due to chemical irritation by acids or alkalies. Systematic dilatation may lead to temporary relief or even to permanent cure of stenosis. Esophagismus is most frequent in hysterical subjects; the variability of the stenosis and the presence of other stigmata furnish the diagnosis. Polypi, if present, are easily removed. Thrush invades the esophagus in marantic children and weak adults. Catarrhal ulcers yield readily to applications of silver nitrate solutions; syphilitic ulcers demand the usual specific treatment. Diverticula may be suspected when patients complain of pain after eating; the pain is usually in the lower sternal region. Occasionally masses of undigested food are discharged, with alkaline mucous and an absence of free hydrochloric acid. Esophageal dilatation is usually an accompaniment of catarrh or stenosis; the esophagoscope shows a lax mucous membrane lying in folds, while the end of the tube can be moved about in various directions. Carcinoma and actinomycosis are accompanied by symptoms of stenosis, marasmus, and fetid odor are late symptoms, while the esophagoscopy permits a diagnosis to be made in the stage of early infiltration. Varicosities occur in hepatic cirrhosis and disturbances of the portal circulation and may result in fatal hemorrhages. When foreign bodies are present in the esophagus, the use of the esophagoscope will often suggest means for their removal without resort to surgical operation. Emetics were formerly employed to further the discharge of foreign bodies, but they are uncertain at best and where sharp objects are present they may cause serious mischief.

Tuberculosis of Female Genitals.—In the presence of extensive ascites which recurred quickly after tapping, unfavorable surroundings, the lymphatic constitution of the patient, the lack of means, the initiation of morbid symptoms by an attack of measles, and an afternoon fever, J. L. DUENAS (*Archives of Pediatrics*, Oct., 1901) performed laparotomy.. He found both ovaries studded with miliary tubercles, and in the left ovary four tuberculous cavities. The right Fallopian tube was filled with cheesy matter, the mucous membrane having been destroyed. The adjacent peritoneum also bore tubercles, but in no part was there fibrinous exudation, purulent collection or adhesions. The uterus and appendages were removed, the peritoneum wiped dry, and the patient is now enjoying good health. The author concludes that in the absence of a bacillary purulent vaginal discharge, primary tuberculosis of the female genital tract cannot be detected.

Clinical Form of Acute Malignant Primitive Endocarditis.—The term *febris pallida* is proposed by L. REVILLIOD (*Revue Méd.*, Sept. 20, 1901) to indicate what he regards as a definitely characterized type of vegetative endocarditis, due to staphylococcus albus. The principal symptoms are (1) a fever which oscillates between 38° and 38.6° C., rarely rising above 39° C.; this fever is extremely obstinate, but is accompanied by almost no subjective symptoms; (2) a pallor of the skin which persists even during the febrile exacerbations. For a considerable period the various bodily functions are normal; the general health is practically unaffected. Then there follows a period of lancinating pains referred to the shoulders and down the arms, moderate anhelation without marked dyspnea; enlargement of the spleen; diminution of the urine, which becomes charged with uric acid and urates. Stethoscopic signs are noticed during this stage. In the terminal period cachexia is marked; there is marked general weakness, emaciation, serous effusion in the thoracic cavity. The disease may last four months or more. In the presence of such a clinical picture, after excluding other diseases and especially discrete miliary tuberculosis, the clinician should suspect this form of infectious endocarditis, which is as malignant in reality as it is benign in appearance.

Infectious Pneumonia.—Pneumonia is not a specific disease, writes W. S. MUIR (*Montreal Med. Jour.*, Sept., 1901), and may be caused by other organisms, but in typical croupous pneumonia the pneumococcus is always present. This organism has also been found in bronchopneumonia, in hypostatic pneumonia associated with pyogenic germs, in influenza pneumonia with the influenza bacillus, in typhoid pneumonia with the typhoid bacillus and even with the colon bacillus, and occasionally in bronchpneumonia with the diphtheria bacillus. The microbe can exist harmlessly in the sputum, but, like the streptococcus, it may become pathogenic and ubiquitous. It has been found in otitis media, meningitis, ulcerative endocarditis, pericarditis, empyema, etc. Rabbits and white mice are very susceptible to it. To find it, stain a cover-glass preparation for 5 to 10 minutes in anilin gentian-violet, drain off and immerse for one-half to two minutes in iodine 1, potassium iodide 2, and water 300 parts. Wash in alcohol till no more color runs off the cover slip, wash in water, dry, and mount.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, OCTOBER 19, 1901.

SILENT?

Silence may mean reserve, it may mean chagrin, it may mean confusion. The gentlemen who did not hesitate to criticise the President's physicians and to offer *post hoc* suggestions as to what might have been done, have kept strangely silent for the last fortnight. There have been no further confidences to the daily press concerning errors in judgment, nor slurs upon the attending surgeons, neither have there been any words of apology, nor any signs of appreciation that their attacks were uncalled for and out of keeping with the dignity of the profession.

It is needless to say that the physicians of the State and country have stood by the President's physicians and that they in turn have appreciated the united spirit of the medical press in condemning those who so unexpectedly and unwarrantably heaped criticisms upon them.

Before the evidence was all in if praise was not forthcoming, silence would have been the more noble part, but since the oracles were so outspoken with such little data, why should they preserve silence now in the presence of the full report?

THE FINAL VERDICT.

The official account of President McKinley's case, including the autopsy, which we print on another page, comes to complete the story which has already been told in part in our earlier numbers.

The clinical report tells its own story. The pathological findings may be briefly summarized as follows: The two wounds in the stomach had been and remained effectually closed by suture, but about each of these was an area of necrosis. Behind the stomach, along the course of the bullet in the posterior wall of the trunk which extended to the upper end of the left kidney there was extensive necrosis of the abundant fat and of the central portion of the pancreas, and this latter organ showed throughout numerous small hemorrhages and areas of gray softening. There was no peritonitis and no bacteria were found in the wall of the necrotic track in the back or in the liquid which bathed it. The pancreas had not been wounded by the bullet, and there was no evidence that pancreatic juice had escaped and come in contact with the injured parts. The injuries do not specify the cause of death, but express the opinion that the changes found in the pancreas were an important factor therein.

With regard to the operation the only question that could fairly be raised is as to the correctness of the decision not to provide drainage through the operation wound, and it seems to us perfectly clear that such drainage could have served no useful purpose and that the determination not to incur its risks was wisely taken. The continued presence of uninfected exudate, which might have been removed by such drainage, could have played no important part in bringing about the fatal result, and the formation of the two sloughs in the wall of the stomach, which apparently would have separated in a short time, if the patient had lived long enough, and caused a promptly fatal peritonitis, would not have been prevented by drainage, but, on the contrary, might have been hastened thereby. Posterior drainage, through the back, was of course wholly out of the question on operative and anatomical grounds.

As to the decision to make no further search for the bullet, there can be no question of its propriety. It was imposed by the operative conditions. The thickness of the anterior abdominal wall, and the evidences of increasing and dangerous shock during the operation—was

supported by universal clinical experience of the harmlessness of such foreign bodies, and was confirmed by the findings of the autopsy which gave no indication that the continuing presence of the bullet had anything whatever to do with the necrotic process along its track or the changes in the pancreas, and furthermore showed that such a search would have been fruitless. The failure to find it at the autopsy is easily explained by the enormous (the term used by the pathologist) deposit of fat into which it was traced and within which it was doubtless imbedded. Even supposing that its position could have been determined at any time, at the operation or later, by the use of the X-rays, can any one think that advantageous use could have been made of the information? Consideration of the operative conditions involved can give but one answer.

While it is to be regretted that the cause of death remains obscure and perhaps undeterminable, we are glad to believe that the official report confirms the opinion of the propriety and skilfulness of the treatment expressed by us in our issue of September 21st, and justifies us in saying that it is a clear and full story of a skilful, judicious operation which failed to save life through no error or eversight but solely because of conditions which could not have been prevented or remedied.

A TRIBUTE TO OLD AGE.

WHEN Cicero wrote "Cato the Elder," he chose this man "who had been old so long, and in his age had surpassed all others in vigor," to be the mouthpiece of his philosophy. It might have been Virchow, the octogenarian scientist, uttering these two thousand year old words.

"One who lives absorbed in his work does not very much notice when old age creeps upon him." "Old age must be resisted and its faults counterbalanced by diligence. It must be fought against as one would fight against disease. Nor must we aid the body alone, but the mind and soul much more, for these also, unless we feed them as we pour oil into a lamp, will be extinguished by old age."

This is the spirit that makes men immortal, and it is this indomitable, indefatigable energy, this twenty-century-old pluck, this youth in old age, that has made Rudolf Virchow the hero as well as the father of German medical science.

Simultaneously, as he approached the portal of his eightieth year, did his pupils, friends and admirers in both continents, rise to their feet to do him honor.

A dinner given at Sherry's on the evening of Saturday, October 12th, was the form in which American physicians celebrated his birthday. And to it came the members of the New York Academy of Medicine, and men of prominence from other cities, men who realized that their knowledge of medical science was based on the foundations that Virchow had been hewing and building through sixty years of tremendous work.

There is perhaps no greater thrill of pleasure than that which comes with the disinterested recognition of the presence of greatness. The societies in New York, Paris, Vienna, Chicago and St. Petersburg, where his birthday was celebrated, felt a sense of envy of their confrères in Berlin who had the privilege of entertaining the person of their noble guest. But though his physical presence was lacking, there were those in New York who successfully conjured the spirit of the master to the birthday board.

Dr. Osler, Dr. Welch, Dr. A. H. Smith, and Dr. Jacobi, all personal friends of Prof. Virchow, gave of their intimate knowledge of his scientific work, his life and character, to those who knew him only through his writing.

The fact that Prof. Virchow's work and fame were to most American physicians signalized by the old modest green pamphlet that has for over fifty years been edited by him, gave Dr. Dana a happy thought, and the menu which he devised had for its cover a facsimile of the *Archiv für pathologische Anatomie und Physiologie, und für klinische Medicin.* Within were two beautifully executed portraits of Prof. Virchow, one reproduced from a photograph given to Dr. A. H. Smith in 1859, and the other taken in old age.

TRAUMATIC NECROSIS OF THE PANCREAS.

SINCE the Buffalo tragedy the subject of traumatism of the pancreas, with attendant necrosis, has had more than a merely clinical and pathological interest for members of the medical profession in America. In a certain sense the subject has become one for popular as well as professional study; at all events while the lay press may not have succeeded in imparting to the popular mind a clear knowledge and understanding of pancreatic necrosis, it has aroused so widespread an interest in the matter that the profession will welcome every relevant clinical report. Not every physician can hope to cite cases of pancreatic necrosis from his own practice, and

yet every one is expected by his patients and friends to have an expert knowledge of the subject.

While serious trauma of the pancreas usually is followed by a speedy fatal termination, exceptions to the rule are to be found in literature. Hahn reported a case of bullet-wound of the liver and pancreas, in which the patient recovered, notwithstanding complete pancreatic perforation, presumably with escape of pancreatic secretion into the surounding tissues. Gessner reported six cases of trauma resulting in pancreatic necrosis.

As to the direct cause of the necrosis several suppositions are admissible. It may be due to escape of pancreatic secretion, with resulting action on the pancreatic tissues and on the intra-abdominal fat; this theory is supported by the fact that necrosis is most frequently observed in the immediate neighborhood of the injury to the gland. Another view presents the necrosis as the direct or primary result of the trauma itself; while a third regards the necrosis as due to bacterial invasion of an injured area.

An interesting case of traumatic necrosis of the pancreas is reported by F. Selberg in the *Berliner klinische Wochenschrift* of Sept. 9, 1901. The patient was kicked by a horse, receiving the blow in the epigastric region through thick clothing which prevented any injury to the skin. He complained first of pain and tenderness in the epigastrium. There was no rise of temperature, no increase of pulse-rate, no abnormal cardiac or pulmonary sign, no swelling, no vomiting. Gradually dyspnea set in, and later examination showed slight swelling, dulness over the lower part of the left lung which afterward changed to flatness, diminished respiratory murmur over the flat thoracic area, abdominal distention with tympanitic percussion note except over the dependent portions of the abdomen, where dull percussion note and slight fluctuation were obtained. The highest temperature recorded in this case was 36.7° C. Two liters of sero-hemorrhagic fluid were removed by puncture and aspiration from the left pleural cavity 19 days after the receipt of the injury; the following day the patient died, attempts at stimulation proving utterly useless. On opening the peritoneal cavity it was found to contain a fibrino-purulent exudate, with intestinal coils matted together. Necrotic areas were found in the great omentum. The head of the pancreas was necrotic, soft and friable. The remainder of the pancreas was hemorrhagic, infiltrated and discolored.

While but few microscopical findings in cases of traumatic pancreatic necrosis have previously been reported, the examination made in this case shows no noteworthy departure from the conditions which are known to exist in non-traumatic cases. Pancreatic disease was not diagnosed during life. The pleural exudate was revealed by the physical signs, and aside from this the case was thought to be one of perforative peritonitis.

THE NEW YORK STATE MEDICAL SOCIETY MEETING.

The first semi-annual meeting of the Medical Society of the State of New York held during the past week here in New York city, a report of whose proceedings will be found in our columns, must have proved a very gratifying success to its projectors. It undoubtedly drew crowded houses to its sessions and reawakened lively interest in the society in New York city. The experiment of a semi-annual meeting in this city in addition to the regular annual meeting in Albany deserves to become a permanent feature. There was but one fault with the meeting; so many papers were offered that there was not due time for their presentation and consideration. This is the recurring complaint at all medical meetings and shows the absolute necessity for some method of selection of papers before all meetings.

The reception given by the New York County Medical Society to the visitors was as enthusiastic a success as any medical event of recent years. The scientific features of this session deserve wide attention from the profession. The symposium on Diseases of the Liver and Bile Passages on Tuesday night brought out the recent views on the principal details of these frequently seen conditions that are at present at the very acme of interest all over the medical world. The discussion on pneumonia initiated by Dr. J. C. Wilson, of Philadelphia was not encouraging from the standpoint of new therapeutic suggestions but it made clear the present position of conservative medical opinion with regard to the failure of supposed specific medication and the routine of treatment that seems most rational to employ. Besides these the papers on tuberculosis and Dr. Howard Kelly's demonstrations of the vascular supply to the kidney were contribu-

tions to medical practice and science that deserve widespread attention.

We welcome the New York State Medical Society and congratulate its officers on the high standard they have set.

THE PATHOLOGICAL INSTITUTE.

THE correlation of sciences in the study of the sciences was the fundamental conception of the old Pathological Institute, and an excellent controlling spirit it is. We are glad to see that the new Institute is to represent this spirit in even a wider sense by the appointment by Commissioner Peterson of several scientists of world-wide reputation.

The Advisory Board just appointed would make an ornament to any institution and New York State is to be congratulated on having a leader who is capable of gaining the coöperation and support of such men.

ECHOES AND NEWS.

NEW YORK.

Appointment of an Advisory Board for the Pathological Institute of the State Hospitals. —The plan of reorganization of the Pathological Institute of the New York State Hospitals for the Insane undertaken by the State Commission in Lunacy is gradually taking shape. In order to add to its efficiency a great deal of careful thought was given to the matter of the appointment of an Advisory Board, whose duty it should be to aid in the development of the Institute and the carrying on of its work on broad lines and to assist the new Director soon to be appointed by its valuable advice. It is the aim of the reorganized Institute to carry on work in the sciences correlated with psychiatry much according to the original scheme, but with a few modifications calculated to meet more immediately the needs of the hospitals as expressed by the superintendents and to meet some of the criticisms of the former plan. Original research in the various sciences having a bearing upon the subject of insanity will go on as before, but in addition thereto the Institute will be utilized to give special instruction in clinical psychiatry, as well as methods of scientific research to the physicians on the staffs of the hospitals for the insane and to young men about to take up an asylum career. In order to obtain this clinical experience the Institution needs to be combined with a hospital for the insane, and to bring this about it is for the present to be connected with one of the asylums on Ward's Island, and until such time as a reception hospital for the insane can be established in Manhattan.

In selecting the members of the Advisory Board, the Lunacy Commission deemed it expedient to have the three University Medical Schools of New York City represented, *viz.*: Columbia, Cornell and Bellevue-University. Furthermore it was considered to accord to the chief sciences correlated with psychiatry representation upon the Advisory Board. These sciences are pathology, chemistry, psychology and general biology. Inasmuch as the Pathological Institute was created for the utilization of the material of all the State hospitals, and for the purpose of raising the standard of scientific study, treatment and care of the insane under State care, it was thought best that these institutions should also have a voice upon the Advisory Board. A member to represent general clinical medicine and neurology was likewise selected.

Accordingly the Commission in Lunacy has established an Advisory Board consisting of the following gentlemen: Dr. J. McKeen Cattell, Professor of Psychology, Columbia University; James Ewing, Professor of Pathology, Medical Department of Cornell University; Dr. Christian A. Herter, Professor of Pathological Chemistry, Bellevue and University Medical College; Hermon C. Bumpus, Assistant to the President of the American Museum of Natural History, to represent the department of General Biology; Dr. Henry Hun, Professor of the Diseases of the Nervous System, Albany Medical College, to represent Neurology and General Clinical Medicine; Dr. Charles W. Pilgrim, Superintendent of the Hudson River State Hospital, at Poughkeepsie, and Dr. A. E. Macdonald, Superintendent of the Manhattan State Hospital, East, to represent the State Hospitals; Dr. Frederick Peterson, President of the Lunacy Commission, a member ex-officio.

All of the appointments to the Advisory Board are permanent except two. The two superintendents of asylums on the Board were elected by the fourteen asylum suprintendents of the State at a meeting held in Buffalo, September 28th, for a term of two years only, thus permitting all of the asylums to be represented in rotation on the Board.

All of the gentlemen selected have accepted their appointments. They serve the State without charge, willingly giving their time and services free for the cause of science and to advance the interests of the insane.

From some of the letters of acceptance the following quotations may be made to observe the spirit in which the appointments have been accepted:

Prof. Cattell writes: "I shall be glad to be a member of the Advisory Board of the Pathological Institute. I have followed the history of the Institute with some care and am much interested in its reorganization on lines that will both advance science and be of use to the hospitals for the insane of the State."

Prof. Ewing writes: "I have always felt an active interest in the permanent success of this institution, and will serve you in any way likely to further that end."

Prof. Herter writes: "I am confident that a board constituted as you propose will prove distinctly helpful in selecting the most promising paths of research. It will be a pleasure to me to do whatever I can to further the usefulness and success of the reconstructed Institute."

Prof. Hun writes: "I have always taken a great interest in the Pathological Institute and I very gladly accept the position which you offer. I stand ready at all times to do all in my power to further the interests of the Institute and its scientific work."

Manhattan Dermatological Society.—A regular monthly meeting of the Manhattan Dermatological Society was held on Friday evening, October 4, 1901, at the residence of Dr. I. P. Obendorfer, No. 1037 Lexington avenue, with Dr. Wm. S. Gottheil in the chair.

Dr. Wm. S. Gottheil presented a child of seven months with *favus corporis*. The interscapular region showed three patches which were typical of the disease. No history of infection could be elicited, nor were any subjective symptoms present.

Dr. E. L. Cocks showed a baby of two months with redness and scaliness of the lower abdomen, buttocks, inner surfaces of the thighs and part of the legs. The case was presented for opinions as to its *syphilitic nature*.

Dr. Kinch inclines toward a diagnosis of syphilis on account of the marked involvement of the lower extremities. Dr. R. Abrahams calls it eczema intertrigo. The absence of hepatic enlargement, snuffles and fissures at the angles of the mouth speak against syphilis. Dr. J. Sobel terms these cases dermatitis erythematosus eczematoides. A case of syphilis with such involvement of the buttocks would show rhagades of the anus and mouth. Dr. Oberndorfer considers it an intertrigo with more intense manifestations than usual. Drs. Bleiman and Geyser exclude syphilis and call it intertrigo. Dr. L. Weiss says the case is typical of seborrheal eczema of the newborn, the lesions in the inguinal region and inner surfaces of the thighs being modified by moisture. Dr. Gottheil calls it seborrheal eczema. Dr. E. L .Cocks in closing stated that he did not regard it as syphilis, but thought that it presented features worthy of differentiation.

Dr. E. L. Cocks presented *three cases of syphilis* in a mother and two children, the former being the primary source of infection. Seven months ago the mother presented herself with a chancre, mucous patches, iritis and a syphilide. In spite of specific directions as to the dangers and consequences of infection, the first child, a girl of 13 years, had a chancre of the right tonsil three months after, and the second girl a syphilide with specific pharyngitis, four months after. Dr. Sobel remarked that cases of family syphilis were not very uncommon, and to put it mildly were deplorable. Dr. Weiss thought that such cases should urge one to have syphilis classified by the Board of Health as a reportable disease. Dr. Gottheil stated that infection through the mouth is not at all uncommon and often explains many obscure and mysterious cases.

Dr. R. Abrahams presented a woman with a *parasitic eczema* of ten years' duration, involving the abdomen and thighs. The flexor surfaces of the arms showed a papular eczema very suggestive of lichen planus. Dr. Kinch thinks it a combination of eczema and lichen planus. Dr. Bleiman calls the arm lesions lichen and the genitals and thighs eczema marginatum. Dr. Oberndorfer considers it an atypical psoriasis. Dr. J. Sobel calls the condition eczema, mycotic on the abdomen and thighs, papular on the forearms. The arms show the retrogressive eczema papules which, as Gottheil states, so closely resemble lichen. Dr. L. Weiss considers it eczema marginatum aggravated by acute attacks. Dr. E. L. Cocks would diagnose eczema and lichen. Dr. Gottheil considers it a mycotic eczema. Dr. Bleiman presented a woman with *vitiligo* of the arms, face, and body.

Dr. J. P. Oberndorfer showed a man with *gumma* of the *glans penis* to demonstrate how difficult at times differentiation from chancroid proves. No history of previous syphilitic infection could be elicited.

Dr. J. Sobel presented a man with *eczema marginatum* of the suprapubic region and thigh.

Dr. R. Abrahams showed a girl of 13 years with *herpes tonsurans maculosus et squamosus*. The body presented scaly patches of various shapes and sizes. Drs. Kinch, Cocks, Oberndorfer, Geyser, Weiss and Gottheil consider it seborrheal eczema. Dr. Bleiman remarked that the involvement of the scalp, forehead and back of the ears spoke for seborrheal eczema. Dr. J. Sobel stated that against pityriasis rosea might be mentioned, the thickness of the scales, their oiliness, the infiltration of the skin and the greater elevation of the lesions.

Dr. R. Abrahams presented a child with a *chronic papular eczema* of the body.

Dr. Oberndorfer would call it lichen acutissimus, Dr. Bleiman keratosis follicularis, Dr. Gottheil congenital follicular keratosis, Dr. Cocks seborrheal dermatitis.

Rockefeller Research Plan.—Plans for the work to be taken up this winter by the Rockefeller Institute for Medical Research, which was founded several months ago by John D. Rockefeller with a fund to begin work with of $200,000, were considered by the Board of Directors at a meeting held Saturday afternoon in this city, and at which all of the men whom Mr. Rockefeller selected to manage the institution were present. It was the second quarterly meeting to be held since the founding of the institute. At it, according to Dr. Holt, who was authorized to give out an outline of the plans decided upon, it was decided to begin the work of research in earnest this winter, and to that end nineteen fellowships were established. The persons having these fellowships will work in laboratories in Chicago, Montreal, Philadelphia, Ann Arbor, Boston, Baltimore and other cities. Only one

is to work abroad and the person to do this has already been selected and is on his way to his new field of labors, which will be in Prof. Ehrlich's laboratory in Germany. This worker is Dr. Marshall, a pupil of Dr. Welch's. Names of the others who will engage in the work of research have not yet been given out, as only a few have been selected. The men who so far have been asked to work for the institute have been engaged for some time in laboratories, and it was by writing to those laboratories and seeking their best workers that the selections were made. This will be done in the case of all the others to be appointed. All the fellowships are for one year, during which time every person holding one will be asked to do original investigating and submit a report of his work to the board, which probably will have it published if it is found to be of value to the medical profession. The investigation of the milk supply of this city, which was the first work to be taken up by the institute, and which went on during the summer, has been completed and a report of it is already in the hands of the directors. Dr. Holt said that possibly it may be made public at some future time, but not at present. The investigation was an exhaustive one, three workers being employed, one to inspect dairies and the transportation; another to do bacteriological work and the third to examine the supply in institutions in relation to the health of the inmates.

Another investigation was also started in the summer, but has not yet been concluded. It was of the germ which causes outbreaks of dysentery and was made by Dr. Flexner of the University of Pennsylvania. Dr. Flexner has already visited two places where such an outbreak occurred, New Haven and Lancaster, Pa., but he has not yet submitted his report. The work to be taken up this winter, Dr. Holt said, would be more in relation to forms of tuberculosis and typhoid fever. It is understood that the work will take on a much more extensive scope next year, but at this time nothing more will be made public.

PHILADELPHIA.

Death of Dr. Everhart.—Dr. John B. Everhart, a prominent physician of West Chester, died October 8th in his seventy-fifth year. He was a graduate of Princeton and of the University of Pennsylvania and served three years as surgeon in the Civil War.

Dr. Kelly Visits Philadelphia.—Dr. Howard A. Kelly of Baltimore lectured before the Y. W. C. A. of the Woman's Medical College October 8th on "Bible Studies." Preceding the lecture Dr. Kelly was the guest of honor at a dinner given by the Faculty of the College and following it a reception was held at the headquarters of the Association.

Changes in Wills Eye Hospital Staff.—After a service of nearly thirty years as attending surgeon at Wills Eye Hospital, Dr. William F. Norris has resigned the position and will become consulting surgeon. Dr. George C. Harlan has been appointed consulting surgeon and Dr. Paul J. Pontin's assistant surgeon.

Dresses Must Not Be Long.—The Board of Health of Pottsville has ordered all women to wear short dresses in order to avoid gathering disease germs in the street and carrying them to their homes. The collection of cigar stumps on the streets is also prohibited.

Split in Hospital Board.—As a result of the election of superintending physician of the Danville Hospital for the Insane, four of the trustees, Drs. Harvey and Detwiler and Messrs. Scarlet and Holloway, tendered their resignations to Governor Stone. They inform the Governor that it is their belief that "the care and treatment of the insane and management of the institution is not what medical skill and modern treatment demand." Dr. H. B. Meredith was reëlected superintending physician for ten years.

Officers of Pathological Society.—At the meeting of the Philadelphia Pathological Society October 10th the following officers were elected for the ensuing year: President, Dr. Charles W. Burr; Secretary, Dr. J. D. Steele; Treasurer, Dr. T. S. Westcott; Recorder, Dr. David Riesman.

Smallpox.—Sixty new cases were reported for the week ending October 12th, an increase of 20 over the previous week, but only 2 deaths occurred. The Municipal Hospital smallpox ward is overcrowded and will be until the temporary structure for these cases is completed next week.

The Aspect of Disease as Seen in Arctic Alaska.—Dr. Ernest W. Kelsey read an instructive paper on the above subject at the meeting of the County Medical Society October 9th, his observations being based on a stay of two summers and one winter in that region. Physicians there must be their own nurse, apothecary, anesthetist, etc., in most instances. Trained nurses command $15 a day and upward. The diseases most prevalent are cerebrospinal meningitis, scurvy, typhoid fever, and neuralgia, the natives, however, being singularly free from scurvy and meningitis. The typhoid fever cases show a tendency toward absence of rash and low temperatures. Traces of scorbutus are often present. The cerebral form is rampant and difficult to differentiate from cerebrospinal meningitis. Hemorrhages followed by perforation are common. The fever is often intermittent in type and quinine is very valuable in such cases. Rheumatism is usually neuralgic in type, the inflammatory form occurring only in the summer time. The heart is rarely attacked. Pneumonia is met with during the spring and summer months, but rarely in cold weather. Nervous diseases are of two types—structural and psychic. The free use of alcohol has much to do with these lesions. When alcohol cannot be obtained all substitutes are used—wood spirit, tabasco sauce, red ink, etc. Insanity is com-

mon. Diseases prevalent among the natives are chronic bronchitis, consumption, smallpox, and pneumonia in the rainy season.

Alvarenga Prize of the College of Physicians of Philadelphia.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about One Hundred and Eighty Dollars, will be made on July 14, 1902, provided that an Essay deemed by the Committee of Award to be worthy of the Prize shall have been offered. Essays intended for competition may be upon any subject in Medicine, but cannot have been published, and must be received by the Secretary of the College on or before May 1, 1902. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the College; other essays will be returned upon application within three months after the award.

The Alvarenga Prize for 1901 has been awarded to Dr. George W. Crile, of Cleveland, Ohio, for his Essay entitled: "An Experimental and Clinical Research into Certain Problems Relating to Surgical Operations."

CHICAGO.

Resolutions on the Death of Dr. Jones.—At a meeting of the Chicago Ophthalmological and Otological Society, held October 8, 1901, the following resolutions were adopted: *Resolved*, That the members of this Society having heard with deep regret of the recent demise of their colleague, Dr. S. J. Jones, desire herewith to express their appreciation of his faithful service in the medical profession of this city, and to testify to the valuable contributions he has made to the subject of ophthalmology. *Resolved*, that a copy of these resolutions be sent to his family.

Resignation of Dr. Dudley.—Dr. C. C. Dudley has resigned the chair of Gynecology at the Northwestern University Medical School, a position which he has filled for many years.

GENERAL.

Laying of Corner-Stone at the University of Michigan.—This ceremony was performed Tuesday, October 15, 1901, An address was delivered by John A. McCorkle, M.D., class of 1873, of Brooklyn. Also an address by Leartus Connor, M.D., of Detroit, president of the Society, with introductory remarks by Honorable Herman Kiefer, chairman of the Committee on the Department of Medicine and Surgery. Remarks were made by President James B. Angell, followed by an address by J. George Adami, M.D., of Montreal.

The Canteen in Its Sanitary Relations.—At the recent meeting of the American Public Health Association at Buffalo the regrettable results of the recent legislation respecting the Army canteen was a prominent topic under consideration. All the Army medical officers present gave strong testimony as to the harmful working of the system established in place of the former canteen, and resolutions deprecating the change were passed unanimously.

Hospital Staff Resigns at New Rochelle.—The physicians comprising the medical staff of the New Rochelle Hospital met October 14th and adopted a resolution notifying the Board of Governors of the institution that after November 1st next they would no longer serve as the physicians at the hospital, and that this action would not be reconsidered unless the board rescinded a recently passed resolution which is distasteful to the doctors. Among the members of the medical staff are Dr. T. P. Berens, Dr. Z. Edwards Lewis, Dr. C. Nelson Raymond, and Dr. L. J. Roberts.

Virchow Dinner Celebration in Berlin.—Prominent men of science from all parts of the world assembled in Berlin, October 12th, to join in the celebration of the eightieth birthday of Professor Virchow. The newspapers devote columns to his eulogy, reviews of his life, instances of his remarkable vitality and incessant work, referring to the fact that he only allows himself four or five hours' sleep daily.

Count von Posadowsky-Wehner, Secretary of the Imperial Home Office; Baron von Richthofen, the Secretary for Foreign Affairs; Herr Thielen, the Minister of Public Works; Herr Moeller, the Minister of Commerce, and other distinguished officials assisted at the ceremonies, which took place at the Pathological Institute. Besides the entire fraternity of medicine of Berlin, there were present deputations from all the German universities. Professor Virchow on entering the hall was warmly greeted. He made a speech which lasted nearly two hours. It was mostly devoted to the development of pathological science. Surgeon-General Schaper then tendered the congratulations. He referred to the gratitude of humanity for the blessings bestowed on the world at large by him whose motto had always been *"Salus populi suprema lex esto"* (Let the people's safety be the supreme law).

The chief function of the evening was a banquet given in the lobby of the lower house of the Prussian Diet, which was attended by a gathering equally as distinguished as that present at the ceremonies during the day. Professor Waldeyer, secretary of the Academy of Science, presented to Professor Virchow 50,000 marks, subscribed by the medical men of Germany to increase the endowment of the Virchow Institute. Dr. Studt announced that Emperor William had conferred upon Professor Virchow the great gold medal for science, and read the Emperor's letter accompanying the decoration, which said in part: "You have broken new ground and laid fresh foundations for medical science. Your name is

written boldly upon the tablets of history, and is honored far beyond the borders of the Fatherland." The King of Italy sent Professor Virchow a gold medallion bearing a portrait of himself.

During the afternoon three Americans, Messrs. Honan, Dickie and Burtis, called on Professor Virchow and, after tendering their congratulations interrogated him as to when he would visit the United States. In reply to their inquiries, the professor said he would make the visit when he was ninety years old.

The issue of October 12th of the *Berliner klinische Wochenschrift* is given over entirely to the Virchow celebration.

SOCIETY PROCEEDINGS.

THE SEMI-ANNUAL MEETING OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Held October 15 and 16, 1901, at the New York Academy of Medicine.

FIRST DAY—OCTOBER 15TH.

Pathogenesis of Narcolepsy.—Dr. Heinrich Stern of New York gave the details of a case of pathological sleepiness with his investigations of the causes of that condition. The patient was a man of thirty-five, born in Ireland, abstainer from alcohol, with no sexual history and suffering from gastric indigestion. Six years ago he first noticed some hyperesthesia of the forehead and some other parasthetic sensations. After this there developed a tendency to attacks of morbid sleepiness at unusual times. Only the exercise of the most brutal will-power enabled him to keep awake when the attack was on him. These attacks were automatic and did not seem to be induced by any habits of the patient. His tendency to sleep was so strong that he said that should he fall into a pool when the attack was on him he almost felt that he could not exert power enough to rise.

General Neurotic Condition.—The patient presents absolutely no hysterical stigmata. There is one marked feature in the case, namely a tendency to hyperidrosis. This is particularly noticeable on the palm of the hand and the soles of the feet. Sweat is very abundant just before an attack comes on. The patient is not rested by his sleep at night, though he sleeps for nine hours or more and always awakes fatigued.

Physical Condition.—Careful physical examination showed the presence of slight dilatation of the stomach, the lower border of this organ being several centimeters below the umbilicus. Examination of the stomach contents showed no pathological condition except the presence of hydrochloric acid; and the urinary examination was negative, except for an excess of chloride. This excessive elimination of chlorides is very marked. The coefficiency of the toxicity of the urine was distinctly below normal. There was no history of infectious disease in the case from early childhood. The liver seemed to be absolutely normal in size and consistency and there was no functional hepatic derangement. The interesting feature of the case was the excessive output of chlorides, which was distinctly greater than the intake. Not only that, but the tendency to sweating also consumed a certain amount of the chlorides and so added to their diminution in the system.

Rôle of Chlorides.—The chlorides are taken into the system and are excreted from it as a rule unchanged. Their rôle within the body is entirely a physical one. They have an important influence on the osmotic tension of fluids within the body. It would seem that the true cause of the narcolepsy was the decrease in osmotic tension due to the excessive excretion of chloride. In the study of other cases with this symptom, this factor has not been noted and it would seem as though a more careful study of eliminative conditions with regard to the chloride will throw some light on this symptom-complex which has hitherto been so obscure in its etiology.

Luetic Narcolepsy.—Dr. Edward Fisher of New York said that there is usually an autointoxication present in those cases of morbid sleepiness in which no organic lesion can be found. It must not be forgotten, however, that most cases of symptomatic sleepiness are due to specific disease of the brain. When the tendency to go to sleep can be connected with no special cause and occurs at any time or place with a tendency to last for indefinite hours, or sometimes days, it is almost pathognomonic of cerebral syphilis. The most frequent cause is in the form of an enteritis. There is no form of this so frequent as that of syphilitic origin.

Other Causes.—Dr. Abraham Jacobi of New York says that undoubtedly lues is the frequent cause of morbid sleepiness. At the first symptom of the development of the condition there is usually an attack of melancholia. This form of the disease, however, occurs only in older persons. In younger patients there are a set of causes that it is important to bear in mind constantly. A boy of sixteen walked into Dr. Jacobi's office only this morning suffering from almost constant sleepiness. He had the open-mouth somewhat blank expression and the snoring breathing of a person with enlarged glandular tissue in the throat. Adenoids are undoubtedly a factor in the production, and a very important one, of morbid sleepiness. In this case, however, the added causative factor was undoubtedly masturbation. This practice had commenced at the age of five or six and had continued every day of the patient's life ever since.

Brain Hyperemia as a Cause.—Dr. Kinnear of Clifton Springs, N. Y., said that in many

cases of morbid sleepiness there is a poor circulation in the lower parts of the body. Patients complain of cold feet and when asked to tell say that they are as tired when they wake up in the morning as on going to bed. This means that there is brain hyperemia and the indication is to draw the blood from the brain to other parts by various means, when normal sleep will be induced. Dr. Stern in closing the discussion said that hyperemia is undoubtedly a cause of sleepiness, but only indirectly. The true cause is a lowering of the osmotic tension of the blood. This in his case, and probably in many other of the reported cases, was undoubtedly due to a diminution of the chlorides in the system. So far, however, he has not been able to accomplish an increase in the chlorides and so relieve his patients.

Cardiac Neuroses.—Dr. James K. Crook of New York said that the subject of neurotic conditions of the heart is in a disturbed state because of the number of terms that have been used for supposed divers conditions. Though we know much about the nervous mechanism of the heart, the inhibitory fibers supplied by the vagus, the accessory fibers and the presence of ganglia in the heart itself, we are not in a condition to state the exact cause for cardiac neuroses. The ganglia of the heart seem to have atrophic influence, but so far no changes have been found in them in pathological conditions. The nervous system seems to be mainly concerned with the regulation of the strength of the heart-beat and its relations to the size of the small arteries, so as to control the circulation.

Gastroptosis and Cardiac Neuroses.—Dr. Achilles Rose of New York said in the discussion that tachycardia must not be used as a name for conditions which represent merely accidental quickenings of the heart. The word paroxysmal should always be used with it and should indicate that the patient is liable to frequent relapses of rapid heart-action without known cause. In many of these cases of paroxysmal tachycardia stomach dilatation is found. In Dr. Rose's experience this dilatation of the stomach is relieved by strapping with adhesive plaster, according to Dr. Rose's method; it also causes a disappearance of the attacks of paroxysmal tachycardia.

Dr. Fisher of New York said that in his experience tachycardia was frequently associated with enteroptosis. Many neurasthenic patients who suffer from attacks of tachycardia are really the victims of prolapse of the hollow viscera of the abdominal cavity and it is this condition particularly that requires careful treatment.

The Medical Profession and Private Charitable Institutions.—Dr. Enoch V. Stoddard of Rochester, N. Y., a Commissioner of the State Board of Charities, read a paper on the official relation of the medical profession to private charitable institutions. He said that public charity, as it is administered by the State, is entirely a business matter. The State does not enter upon it for altruistic reasons, but because there is the realization that the indigent classes, when uncared for, take on certain tendencies to active dissatisfaction. It is quite different, however, with regard to institutions founded by private charity. To these the doctor owes his personal service and then his duty to science and in the collection of statistics. Very frequently there is no medical man on the board of managers. Hence the difficulties that frequently arise, though some of them get along very well for years. There has been an unnecessary multiplication of these institutions and the new Charter of the State of New York makes it somewhat less easy to establish them. It is probable that more of these institutions will not be founded for some years. Existing institutions must be improved then. There are 35,000 inmates in such institutions in New York State and the valuable amount of statistical material is constantly going to loss. It seems important that the profession should exert itself to secure proper recognition in the management of these institutions and should encourage the collection of the statistics they afford.

Cerebral Apoplexy.—Dr. Edward D. Fisher of New York said that apoplexy need not necessarily be associated with paralysis. At times the arterial rupture in the brain occurs at a part remote from the motor areas. In such cases there may be other symptoms, loss of memory, a tendency to laugh or to cry without reason, a loss of the sense of one's surroundings. In these cases there is always a general atheroma of the arterial system and early in its development this affects the kidneys. Interstitial nephritis ensues and is followed by hypertrophy of the heart which readily endangers the diseased arteries in the brain. Urinary secretion forms an important index of danger in these cases. Persistent low specific gravity points to progressive arterial degeneration. This may culminate in apoplexy in patients of careless habits, but the apoplectic attack may be cut off for years by the avoidance of excess.

Alcohol in Apoplexy.—In Dr. Fisher's opinion steady drinking of a certain amount of alcohol every day, especially in men of sedentary habits somewhat advanced in years, is of much more danger than periodical excess in the taking of alcohol. Often these people are unaware of the amount of alcohol they are taking. Syphilis is also an important cause. These three conditions arteriosclerosis, alcohol and syphilis constitute the etiology of 90 per cent. of all the cases.

Anomalous Apoplexy.—There are certain forms of cerebral disturbances that are due to temporary arrest of cerebral circulation. This is what used to be called serous apoplexy and is undoubtedly due to localized cerebral edema.

No pathological change is found postmortem and these conditions used to be thought due to uremia. Astasis of circulation occurs with the symptoms of an arterial rupture in the brain. In older people these sometimes take on an epileptiform character, though essential epilepsy never develops after twenty-five. Often apoplectic patients complain of pain in the paralyzed limbs, but this is psychical and not due to a true painful condition.

Gouty Apoplectic Attacks.—Dr. William Browning of Brooklyn said that serous apoplexy occurs especially in persons of gouty habit. Often the administration of a laxative will relieve the symptoms in these conditions. Where a number of these attacks of supposed serous apoplexy occur at autopsy there will often be found the remains of slight hemorrhages. There will be found an atrophy much greater than usual in the limb complained of and this seems to be due to a local neuritis. When the trophic influence of the brain is lost a neuritis held in abeyance before becomes active.

Dr. Jacobi said that there is undoubtedly a true passing apoplexy in which after the interruption of the cerebral circulation in a part of the brain the collateral circulation is rapidly reëstablished and the apoplectic symptoms disappear.

Dr. Elsner of Syracuse said that attacks of serous apoplexy so-called are sometimes due to limited areas of edema of the brain left after uremic convulsions. Localized edema of the motor area causes transitory paralysis.

Causes of Apoplexy.—Dr. Spratling of Sonyea, N. Y., said that 85 per cent. of the cases of epilepsy occur before adult life. Epilepsy after the twentieth year is different from that which develops before. It is the epilepsy of early life that oftenest produces unsoundness of mind. This is because it has a systemic basis. Heredity is a very marked feature in the etiology. Epilepsy occurs in parent and offspring in 16 per cent. of all the cases at the Colony. Alcoholism in the parents is found in 14 per cent., insanity in 8 per cent., and tuberculosis in 13 per cent. This accounts for more than one-half of all the cases. Undoubtedly many cases of early epilepsy develop as the result of birth injuries.

Treatment of Epilepsy.—The bromides are undoubtedly the best remedy to control, but not to cure epilepsy. Owing to the depressing effect upon the system they should be used in combination with narcotics, nutritives, alteratives, baths, enteroclysis, and constant care of the dietary, the amount of exercise, the amount of sleep and the regulation of the daily life. In order to have the system take up bromides better, sodium bromide has been substituted for common salt as a condiment for the food. This proves an excellent method of administering it. Of late an organic compound of bromo-bromine-bromopin has been used. This does not produce constipation, nor hebetude, nor acne. An advantage is that it may be used in the status epilepticus hypodermically without producing abscesses. Surgery sometimes does good in epilepsy but not very often. In one case of Jacksonian epilepsy, with the aura always in the first joint of the thumb, there were nearly 500 attacks in 50 hours. The brain was examined very carefully by a pathologist who was unable to find any pathological change in it.

Asphyxia and Epilepsy.—Dr. Jacobi in the discussion said that asphyxia in the newborn is a frequent cause of cerebral disturbance in later life. The longer asphyxia has continued the more surely will serious conditions ensue. The first care of the obstetrician then must be its relief. If there is a question of the mother and the child, the child must be attended to rather than the mother. In case of severe bleeding on the part of the mother it may be necessary to ask one of the family to make firm pressure upon the uterus, for the doctor must give his attention to the child. Dr. Jacobi suggests that if necessary the doctor should sit on the uterus and devote himself to the child. In Dr. Jacobi's experience dentition does not cause epilepsy, though some concomitant disease may prove a reflex source of epileptic seizures.

Premature Ossification.—Premature ossification of the fontanelles is an important cause of epilepsy and idiocy. These openings should close from the tenth to the sixteenth month. If they are closed at birth or if they close in early infant life at from three to six months, the brain has less chance to develop normally. Epileptic conditions later in life are often due to this cause. This must be distinguished, however, from true microcephalus in which there is failure of the brain to develop and consequent smallness of the skull.

Spinal Anesthesia.—Dr. Willy Meyer of New York said that spinal anesthesia is undoubtedly going to take an important place in modern surgery. Certain momentous questions, however, need to be answered and every careful surgeon who employs this method should note the details of every operation so as to enable us to solve these questions. For instance, should some cerebrospinal fluid be removed before the injection? Should this cerebrospinal fluid be used as the solvent of the cocaine which is to be introduced? Should the injection be made slowly or rapidly? What is the most favorable position of the patient? Should the solution injected be concentrated and what should be its temperature? Answers to these questions will enable us to use this method that we owe in large part to American inventive genius with much more security and assurance.

Question of Drugs.—There are undoubtedly certain inconveniences attached at times to the injection of cocaine. Thus far ordinary co-

caine has been employed, but there is no certainty as to whether betacocaine or tropacocaine might not be employed with less fear of sequelæ. Karschbaum introduced tropacocaine to the profession and in ordinary local anesthesia it certainly has much less after-effect than ordinary cocaine. Solutions for spinal injections should be made fresh for each patient. In Dr. Meyer's work on animals a solution that stood for a week had lost much of its anesthetic properties. When kept for two weeks it was useless. Spinal anesthesia is especially indicated in operations upon the kidney.

Inconvenience of Spinal Anesthesia.—Dr. Mynter of Buffalo said that in one case in which he used spinal anesthesia in an old man for a radical operation for hernia, projectile vomiting occurred. This led to the protrusion of all the intestines through the opening made in the abdominal wall. After their reduction, vomiting recurred once more with a second protrusion of the intestines. When the patient sat up to vomit his intestines were spread out on his abdomen. Where such a complication is feared, spinal anesthesia should not be used.

Prolonged Medication.—Dr. Jacobi of New York said that contrary to the opinion held by some authorities digitalis may be employed over prolonged periods. In cases of acute dilatation of the heart where there is great cyanosis and serious disturbance of the circulation, large doses may be employed and repeated several times until the effect is obtained. Dr. Jacobi does not hesitate to employ a dose of ten to twelve grains of digitalis, repeated once or even twice at intervals of four or five hours, until the serious acute condition is overcome. In chronic loss of compensation, he uses four to six grains of digitalis daily for weeks, or even months, and has no fear of its cumulative effect. Dr. Jacobi usually employs four to six drops of Squibbs' fluid extract per day combined with sparteine, or arsenic, or strychnine. Further details will be found in Dr. Jacobi's article which is to appear in the Medical News.

The President's Case.—Dr. Matthew D. Mann of Buffalo then read abstracts from the autopsy on the late President, which will be found complete in another part of this week's News, and gave some account of the case. Dr. Mynter of Buffalo, another medical attendant on the late President, said that now, after the autopsy and the thorough discussion of the case, there was no doubt in his mind that if the President had to be treated over again he would be treated in exactly the same way as he was. The exact cause of death was unknown. It was probably due to the patient's very sedentary life and lowered vitality.

Early Diagnosis of Pulmonary Tuberculosis.—Dr. J. E. Stubbert of Liberty, N. Y., said that the Roentgen rays are of special service in the diagnosis of early forms of pulmonary tuberculosis. He showed a series of radiograms with a stereopticon that illustrated how much information might be obtained from this method of examination. Very early changes in the lung, especially such changes as occur beneath the surface and which can not be detected by ordinary methods of physical examination are brought out very clearly by the Roentgen rays.

Treatment of Tuberculosis.—Dr. Stubbert said that no worse advice could be given to a person than that sometimes given by family physicians. They say "Go to the country for a while and keep away from doctors." Unless the patient is under the care of a physician serious mistakes will be made and the progress of the case delayed. More improvement will come from treatment in New York City under the care of a physician than in the country without one. In Dr. Stubbert's experience pathological conditions of the nasopharynx often exist and these hinder improvement. It should be a routine practice to examine the upper air-passages of all patients suffering from or suspected of suffering from tuberculosis and then the existing pathological conditions should be treated.

Drug Treatment.—Drugs are important in the treatment of tuberculosis. Where anemia exists, iron and arsenic should be used and static electricity and hydrotherapy employed. Exposure of the patient to the parallel rays of the electric arc will be found of excellent service. Patients should, of course, be advised to eat heartily, but there is almost more danger of overfeeding and consequent disturbance of digestion than there is of underfeeding. When tuberculous patients began to convalesce their appetites are often enormous. Under these circumstances it is important that tonic medicine should be carefully employed and the digestive tract kept in as good condition as possible.

Tuberculosis and Endocarditis.—Dr. J. M. Anders of Philadelphia said that in certain cases of endocarditis, tubercle bacilli have been found in the lesions. As a rule, however, primary tuberculosis of the endocardium is not seen. The endocardium becomes involved secondarily in cases of miliary tuberculosis and at times, also, when there is extensive involvement of the mediastinal glands. The endocardium acts as a protector against tubercle invasion. In this respect it is very much like the inner coating of the blood-vessels. The intima of the blood-vessels is very seldom affected primarily by tuberculous processes and tuberculosis when found occurs in the other coat of the vessels. Tuberculosis of the endocardium can only be diagnosed by exclusion.

Heart Lesions and Tuberculosis.—Long ago Rokitansky said that enlarged heart protected patients from tuberculosis. Traube, Niemeyer and other German authorities were not quite as absolute in this opinion as Rokitansky, but

they agreed that heart lesions served to ward off tuberculosis. According to statistics tuberculosis is less in people with heart disease, but the protection afforded is variable according to the orifice at which the lesion occurs. Of late, moreover, the more careful collation of statistics has shown that heart cases are not spared tuberculosis as often as has been thought. Clinically, in cases of tuberculosis, heart lesions are found in less than 2 per cent. Of the cases, at autopsy, however, according to a recent set of statistics, 16 per cent. of the tuberculous have heart lesions. There are two reasons for this discrepancy: One is that the heart lesion often escapes notice. The other is that the tuberculous process is sometimes latent.

Reason for Protection.—It has been thought that the protection afforded by a heart lesion was due to congestion of the lungs. Abrams pointed out, however, that when loss of compensation occurred tuberculosis of the lungs often becomes fulminant in character. He attributes it to hypertrophy of the heart. It is well known that a small heart predisposes to tuberculosis. Hemoptysis relieves congestion of the lungs, and yet, as is well recognized, often slows the progress of pulmonary tuberculosis. It is probable then that the better circulation in the lungs from a hypertrophied heart has much to do with the protection afforded.

The Uterine Muscle in Displacements.—Dr. Henry C. Coe of New York called attention to the fact that in many cases of prolapse of the uterus with ante- or retroflection it is not so much the position of the uterus as the lack of muscular tone that is responsible for the symptoms. The uterus falls down below the normal plane in the pelvis and then comes the headache, dragging feeling, dyspepsia and other symptoms. A series of operations may be done, relieving the malposition, but if the lack of tone of the muscles continues, the symptoms will not be relieved. The general condition of the patient must be taken into account. The muscular tone must be increased and patients must not be assured of complete recovery by operation alone.

In discussing Dr. Coe's paper, Dr. Grandin said that the symptoms in these cases depend on the sagging and not the tilting forward or backward of the uterus. The improvement of muscular tone must always be borne in mind as an important factor for the relief of the symptoms, but no relief will come unless the uterus is suspended, either by Alexander's method, or from the abdominal wall.

Abdominal Actinomycosis.—Dr. Van der Veer of Albany reported a case of abdominal actinomycosis. The patient was thought to be suffering from sarcoma. So many adhesions were found, however, at operation that it was concluded that some form of chronic granuloma was present. No origin for the disease could be found except that the patient was frequently in contact with hay and straw in feeding animals. The patient is about to make a good recovery under simple drainage. Dr. Van der Veer found iodide of potash of distinct service in the treatment of the case, and also Fowler's solution. He suggests the more careful preparation of grains for food. It is possible in cereals that the actinomyces fungus finds a way into the human subject.

EVENING SESSION.

Symposium on Some Diseases of the Liver and Bile Passages.

Aberrances of Gall-Stones.—Dr. Charles G. Stockton of Buffalo discussed the diagnosis of gall-stones and especially the anomalous symptoms they not infrequently presented. Gall-stones are now generally conceded to be due to infections. Their frequency is much greater than has been thought. At autopsy 25 per cent. of all women over 60 present gall-stones, although 90 per cent. of these cases have never presented any symptoms of the condition. The original formation of most gall-stones is due to an infectious process set up in the gall-bladder and acute attacks of gall-stone colic are usually brought into exacerbations of this infectious process. The question especially of the intermittency of the jaundice and the probable origin of this condition in a ball-valve action of the gall-stones in the biliary duct was touched upon.

Gall-Stone Fever.—Dr. Stockton used to be decidedly of the opinion that when in the midst of a severe paroxysm of pain referred mainly to the right hypochondriac region a rigor occurred, followed by high temperature and a tendency to collapse, these symptoms were sufficient to indicate with assurance the presence of a purulent process in the biliary region. Further experience has convinced him, however, that all of these symptoms may occur with only an ordinary attack of gall-stone colic without any suppuration. An important differential diagnosis is that which must be made from gastralgia. It is not easy to make as a rule. The chief symptoms of gall-stone colic on which special significance must be placed for differential diagnostic purposes are paroxysmal pains, tenderness in the region of the ninth rib on the right side, vomiting, ague-like attacks of fever, jaundice with collapse and calculi in the stools.

Courvoisier's Law.—Dr. Richard C. Cabot of Boston, Mass., said that about three years ago, while examining a case with evident biliary symptoms a colleague referred to Courvoisier's law. When he expressed his ignorance of it, the colleague referred him to Osler. There he found the law which was established by the Basel surgeon in 1890. As the law is important for the diagnosis of biliary conditions and as others may not be aware of its existence a statement of it seems not inoppor-

tune. Simply put, Courvoisier found as the result of a series of clinical observations that when there was obstruction of the bile-ducts by gall-stones, enlargement of the gall-bladder is extremely rare. If, however, the obstruction of the gall-duct is due to other pathological conditions then obstruction is almost the rule. He studied 187 cases of biliary conditions before announcing this conclusion. Of these 87 were of gall-stone origin and 70 of them presented atrophied gall-bladders. One hundred patients suffered for other reasons than gall-stones, and in these 92 had distended gall-bladders.

Confirmation of the Law.—In 1892 Mayo Robson, an English surgeon, evidently without knowing that his conclusions in the matter had been anticipated by the Swiss surgeon, announced that jaundice with distention of the gall-bladder indicated the presence of a malignant tumor obstructing the bile-duct. When there was no distention of the gall-bladder the obstructing agent was commonly gall-stones. Professor Naunyn of Strasburg considered Courvoisier's law well established.

American Teaching.—Curiously enough Courvoisier's law seems to have escaped the attention of most of the writers of text-books in America. Many of them state very simply on general principles that when there is an obstruction of the bile-duct distention of the gall-bladder takes place. Carrying the theory still further, some of the important text-books state that in cases of gall-stones distention of the gall-bladder may be looked for, and when it is found, the presence of a gall-stone may be diagnosed.

Confirmation of Law by Boston Cases.—Dr. Cabot searched the records of the Massachusetts General Hospital. Here he found ample confirmation of the law. In 86 cases of gall-stones in which the hospital record gave sufficient details to enable one to come to a decision as to the presence or absence of distention of the gall-bladder only four violated Courvoisier's rule. When gall-stones were present with the exception of a single case the gall-bladder was not found distended, but either spasmodically contracted or atrophied. In all malignant cases the gall-bladder was noted as distended with two exceptions, there being one doubtful case.

Infections of Gall-Bladder.—Dr. B. Farquhar Curtis of New York replaced Dr. Maurice Richardson, absent through illness, in an article on this subject. Dr. Curtis said that formerly bile was thought to be sterile. Bile checked yeast fermentation and was thought to be germicidal in its action. Normal bile has been found, however, not to be a germicide and the duodenum is as sterile without bile as with it. American observers have shown that two-thirds of the bile of patients operated upon contains microbes. These microbes find an entrance through the duct, or, at times, through the bladder. Infection through the bladder is sometimes considered a far-fetched notion, but it has been shown experimentally that the injection of typhoid bacilli into the blood of animals may lead to the presence of typhoid bacilli in the gall-bladder.

Favoring Conditions.—The presence of foreign bodies in the biliary passages or of any condition that obstructs the flow of bile favors the occurrence of infection. Where gall-stones are present infection almost invariably takes place. Dr. Curtis has seen a case recently in which jaundice lasted for many years. The patient died after an operation for appendicitis and a peculiar condition of flexure of the bile-duct was found. This flexure seemed to be due to a congenital prolongation of the duct and acted as a valve. Hence the intermittence of the jaundice of the case. The family history showed that a brother of the patient had suffered from intermittent jaundice for many years. Their mother had been affected the same way for most of her life.

Consequences of Gall-Stone.—Dr. Curtis considers that acute peritonitis from complications due to the presence of gall-stones is much more frequent than has been thought. The prognosis of these cases is much worse than has usually been considered. Many of the more or less sudden and unexplained peritonitides are due to complications and sequelæ of gall-stones. The differential diagnosis between an attack of gall-stones and appendicitis is not always easy to make. It is not an uncommon thing for the present-day surgeon to open an abscess on the right side of the abdomen midway between the appendix and the gall-bladder without knowing to which of these important and dangerous organs the pathological condition may be due. The mere evacuation of the pus does not always tell the story of its origin, and it is not until gall-stones are found in it that it can surely be concluded to be due to biliary conditions.

Technic of Gall-Stone Surgery.—Dr. S. J. Mixter of Boston said he considered the use of rubber gloves in gall-stone operations a mistake. The operation is done in the depths of the abdomen and the sense of touch is extremely important and is much blunted by the use of gloves. A careless surgeon may easily miss small stones in the duct and this will, of course, give rise to recurrences or may prevent the operation from having any good effects. Palpation of the duct can be best accomplished through the foramen of Winslow. The surgeon's exploration can be made most readily by turning his back to the patient, which thus gives him the anterior surface of his finger for palpation.

Evacuation of Fluid.—If there is considerable amount of fluid in the gall-bladder, it should be emptied by trocar. The question of drainage is always important and Dr. Mixter always employs it even though the gall-fluid

seems to be sterile or apparently normal. Dr. Mixter has done the so-called ideal operation of sewing up the gall-bladder, but does it no more, because of fatalities that he has seen, though fortunately not in his own experience. The ideal operation is by no means ideal. For drainage Dr. Mixter inserts a flaring glass tube which is tied into the gall-bladder. This is simpler, neater and causes less pain and dragging than the sewing of the gall-bladder to the abdominal walls.

Oozing after Operation.—For the ghastly fatal oozing that sometimes occurs after operation, Dr. Mixter uses fine gelatin carefully sterilized, to which a little adrenalin is added for the purpose of producing hemostasis. Fortunately these cases are extremely rare for they constitute one of the series opprobria of gall-stone surgery.

Cholecystectomy.—Dr. Charles L. Gibson of New York said that drainage in gall-stone cases is by no means a radical operation and the possibilities of a recurrence are not relieved. Kehr, the German authority to whom we owe so much, found that after drainage in nearly seventy per cent. of the cases some symptoms of the biliary condition returned. After extirpation of the gall-bladder, however, he found recurrence of symptoms in only one of the cases. Removal of the gall-bladder is certainly in the line of preventive medicine, the great desideratum of the present day. Cancer of the gall-bladder develops in about 14 per cent. of the cases of gall-stone. The removal of the gall-bladder would prevent the development of cancer and so is an important prophylactic. The operation of cholecystectomy is comparatively simple and the value of the gall-bladder as a reservoir is doubtful; there is no need of keeping it, as is sometimes urged, as a guide in future operations.

SECOND DAY—WEDNESDAY, OCTOBER 16TH.

Medical Aspects of Appendicitis.—Dr. W. E. Ford of Utica said that some of the difference between the statistics of appendicitis in this country and in Europe was undoubtedly due to the fact that the European common people ate different food and were not so much in the habit of bolting their food. Appendicitis is especially common in America among young athletes. This is probably not due to any action of the psoas muscle notwithstanding the claims made in this direction. Traumatism is not a frequent direct cause of appendicitis, though Dr. Ford recalled two cases in which it seems to be the determining cause. In these cases there would seem to have been some pathological conditions preceding the injury. It is probable that a normal, freely moving appendix could not be injured directly. As the result of clinical experience it would seem better to give a light hypodermic of morphine than to give drugs by the mouth. Dr. Ford does not think that the awful warning usually fulminated against the giving of opiates, that it masks the symptoms, is quite deserved. When patients have severe pain it may be relieved by a morphine injection, though of course this should not be repeated. The most prominent medical indication is for catharsis. An ice coil should be placed on the abdomen for 24 hours. After this palpation will show the presence of appendicitis by offensive fulness and the spasm of the rectus muscle. If the temperature and pulse continue normal in 24 hours usually no operation will be needed. If after 48 hours there is rise in pulse and temperature the immediate operation is indicated. If palpation shows extreme tenderness then the indication is for immediate operation. If there is a sudden cessation of pain, perforation or gangrene has probably taken place and operation must not be delayed.

Significance of Tumor.—The presence of a tumor does not necessarily indicate pus formation. Catarrhal appendicitis may well give rise to swelling. As soon as tumors form operation is not necessarily indicated. There are many who think that operation at the earliest moment possible is the idea. Dr. Ford has not seen the best results in very early operations. The only cases in which he has to reoperate because of intestinal obstruction are those in which operation had been done very early with consequent diffusion of the inflammatory exudate and the formation of more extensive adhesions than are usually the rule.

Interval Operations.—After a single attack of catarrhal appendicitis should the patient be operated upon? Sometimes such attacks do not recur. If the attacks are repeated and the health becomes impaired because of the consequent disturbance of digestion then operation should certainly be counseled. If there is more than one recurrence then operation is at least advisable. Dr. Ford does not believe in the continued use of cathartics. The patient should not be kept absolutely on a milk diet, but should be given rice and soft pulpy foods.

No Medical Aspects.—Dr. Herman Mynter of Buffalo said that he did not know that there were any medical aspects to true appendicitis. Professor Ewald of Berlin, one of the most distinguished authorities in the medical aspect of stomach and intestinal diseases, has asserted over and over again that appendicitis is not a medical but a surgical disease. The appendix is an organ of low vitality with large absorbing surface in which micro-organisms from the intestines are liable to become imprisoned and which because of its single arterial blood supply is liable to become gangrenous from the stoppage of that blood supply. The conditions which develop in it then are those of serious inflammation liable to become purulent. For such conditions medicine can do nothing and it is self deceit to pretend that it can.

Catarrhal Appendicitis a Bad Term.—Dr. Robert Morris of New York said that the word

catarrhal as applied to appendicitis has been a most fatal term. Catarrhal appendicitis is probably without symptoms. Whenever appendicitis presents itself for treatment it has gone beyond the catarrhal stage. The use of the word, however, has encouraged the idea that there may be an inflammatory condition in the appendix giving symptoms and capable of complete restoration to health. Dr. Morris is of the opinion that trauma has something to do with the development of appendicitis and he thinks that the psoas is able to twist many appendices.

Heredity and Etiology of Insanity.—Dr. Carlos F. MacDonald of New York read a paper in which he brought out the growing tendency of psychiatrists to consider heredity as the most important factor in the etiology of insanity. There are three forms of mental disturbance in which the influence of heredity is especially noteworthy. These are idiocy, imbecility and degeneracy. The presence of hereditary predisposition causes emotional strain and overwork to affect certain people much more than others. The usually cited causes of insanity, such as the loss of money, loss of friends, failure in business, failure in chosen careers, occur to most people and yet most people are comparatively sane. An insane strain in a family stock is the basis on which mental disturbance develops, though we do not know the modus operandi of hereditary influence. This is especially true in the so-called functional insanity.

Pathology of Migraine.—Dr. William H. Thomson said that migraine is not a degenerative neurosis that occurs like certain forms of neuralgia late in life when people are breaking down, but occurs mainly early in life and may disappear after fifty. Migraine is a class disease and certain classes of people do not suffer from it. Sailors, farmers and workmen engaged in outdoor occupations, or people who are accustomed to considerable exercise in the open air are never affected by it. Clergymen, students, business men, workers in sedentary indoor occupations, housewives, shopgirls and so forth, are the special subjects of it. It is probable that in this distinction of the people who are liable and those who are immune to it we have the physical basis of the disease. The difference in the habits of the two classes of people are especially those which affect the portal circulation. This is the weakest part of the circulation of the body. It has the least share of the force of the heart and the blood must find its own way through the second set of capillaries in the liver substances the walls of which are not elastic. The portal circulation depends then on the adjuvants to the circulation. Of these the most important are the respiratory movements. The up and down movement of the diaphragm and the corresponding movements of the abdominal muscles in deep breathing have an easily recognizable influence upon the flow of blood in the portal veins. How important these muscular movements may be as regards pathological processes we can gather very well out of the fact that one out of every four women suffer from gall-stones after the age of fifty.

The Liver as a Manufacturer of Antitoxins.—One of the main functions of the liver is undoubtedly to neutralize certain poisonous substances which are entering the circulation through the gastrointestinal tract. These substances have a special tendency to act upon the liver. It may easily be understood then how the lowering of hepatic function can lead to nervous painful conditions. Heredity is another important factor in the causation of migraine and there is nothing that is more hereditary than digestive disturbances.

Treatment of Attacks.—All severe cases of migraine are associated with chronic dyspepsia, but especially chronic constipation. For this a five-grain blue mass pill given once a week and followed by a saline the next morning is part of the routine treatment. Mercury undoubtedly provides our best intestinal antiseptic. Every morning one or two drams of sodium sulphate and ten grains of sodium salicylate, should be taken in a glass of hot water. Some prefer to use sodium phosphate, but the sodium sulphate is more satisfactory. Besides this there should be daily ten grain doses of phenol or naphthol bismuth, or of the sulpho-carbolate of bismuth. For the actual attacks themselves, dram doses of pure extract of ergot are the best remedy to cut them short. Patients should remain quiet after the administration of the drug and the dose may be repeated after an hour if necessary. For some patients 15 grains of antipyrin is an excellent remedy. This should never be given except in association with a dram dose of aromatic spirits of ammonia. It is important to regulate the diet of migraine patients and yet not very much can be said as to a definite set of rules. As a rule pale and anemic individuals should be encouraged to eat more than before. Red meats, however, should be avoided to a large extent and especially should not be taken at night. One dietetic rule can always be given with more or less assurance, that is if anything is tasted again after being swallowed or in the midst of gaseous eructations, this is to be a sign that the stomach does not want that stuff any more. Generally migraine occurs during the years when the nervous system is overtaxed by worry. If we can make the attacks of migraine less frequent we are not only conferring a present benefit on the patient, but we must not forget that it is in these patients particularly that melancholia is apt to develop. It is well known now that intestinal antisepsis is important for the prophylaxis of melancholia and so we may be doing our patients a double benefit.

Other Drugs.—Dr. Jacobi in discussion said that the migraine may occur in very early years, even at three or four or five years of age. Usually the patients are pale and underweight and sleep better without a pillow. The vomiting that so often occurs in migraine is another sign that the patients are suffering from cerebral anemia.

Counteract this and much is done to benefit them. Dr. Jacobi has found aconite the best drug, though the American preparation gives no benefit and only the French aconitine of Duquesnal succeeds. Cannabis indica, the English preparation, is another effective remedy. This should be given in doses of the extract, one-half to three-fourths of a grain. Dr. Jacobi also employs strychnine and arsenic and believes that combinations of drugs are very effective.

Perinephritic Hemorrhage: Non-Traumatic.—Dr. Arthur Booth of Elmira presented the report of a case in which the patient died from hemorrhage in the neighborhood of the kidney without any trauma to occasion it. The man had been a somewhat heavy drinker since his college days and the arterial changes consequent upon this would seem to have been the reason for the hemorrhage. Seventeen days after the acute pain that accompanied the first hemorrhage, he was prepared for operation, but died suddenly before the operation was begun. The clot around the kidney was laminated and partly organized and the successive hemorrhages seemed to occur when the clot contracted. Spontaneous kidney hemorrhage is extremely rare in adults, but not uncommon in children.

Nephropexy.—Dr. George Edebohls of New York said that in cases of floating right kidney he often finds chronic appendicitis present and removes the appendix at the time of the kidney operation. At the same time owing to the frequency of biliary disease in women, he palpates the biliary passages. He no longer uses sutures through the kidney substance itself in order to anchor the kidney, because the presence of the suture may lead to urinary fistula. He has operated upon 261 kidneys in 193 patients and has lost only two patients.

Uterine Bisection.—Dr. W. G. MacDonald of Albany demonstrated a series of specimens in which uteri bound down by adhesions were easily removed by bisection. In certain cases the use of electricity and the curette in the treatment of uterine conditions leads to the formation of firm adhesions. Fibroid tumors have a like effect. In these cases the bisection of the uterus, either in a vertical or horizontal plane, often renders extremely difficult operations simple.

Priority in Bisection.—Dr. Howard Kelly of Baltimore said that undoubtedly Dr. MacDonald of Albany had been the first to do bisection of the uterus in the cure of severe conditions. Dr. J. Faure had also seen the usefulness of this operation. Dr. Kelly thinks that this bit of technic has done more for the improvement of gynecology than any method introduced in the last 15 years. It makes difficult cases that were frequently lost before comparatively simple.

Kidney Incision for Stone.—Dr. Howard Kelly demonstrated by a series of preparations and specimens how the incision for stone should be made in diseased kidneys. His assistant Mr. Bradel rediscovered the fact pointed out by Hyrtl some years ago, but lost sight of, that the kidney circulation was in two distinct parts. The anterior and posterior parts of the kidney are supplied by distinct sets of arteries. If the incision can be made between the circulations very little bleeding occurs. There is a white line on the posterior surface of the kidney pointed out by Dr. Bradel, which Dr. Kelly proposes to call the Bradel line, that is an index as to where the incision should be made. The incision must be made parallel to the surface of the kidney, and not transversely into the pelvis.

Are the Tonsils Normal?—Dr. F. H. Bosworth, of New York, said that the question of the normality of the tonsils is an open one. In many tonsils there is a mass of tissue containing a blind duct and some lacunar follicles and some lymphoid tissue. Other tonsils contain only lymphoid bodies and there is question whether these latter tonsils are not the really normal structures. As a matter of fact there is in many throats a ring of tonsillar tissue, consisting of four organs, Luschka's tonsil, the lingual tonsil and two faucial tonsils. The deep lacunæ or crypts which occur in some tonsils are certainly adventitious and pathological, and form traps for infectious micro-organisms. Twenty years ago, Dr. Bosworth said before the Laryngological Congress in London that there were perhaps no tonsils in health. He is ready to repeat this now after years of further experience.

Removal of Tonsils.—The notion that the tonsils are usually pathological, would be good for the laity to have for then they would be ready to accept the idea of having them removed. Whenever the tonsils give symptoms in early life they should be removed. Dr. Bosworth prefers the cold snare to the tonsillotome. Partial removal is the worst thing that could happen because it lays the lymphoid tissue open to easier infection. With the cold snare all danger of hemorrhage is removed. In children this is not a serious consideration, but at 12 or 14 years of age hemorrhage may prove alarming. After 15 it is positively dangerous. Dr. Bosworth uses chloroform anesthesia to relaxation not to complete narcosis and in many hundreds of cases has never had the slightest symptom.

Prognosis of Croupous Pneumonia.—Dr. J. C. Wilson of Philadelphia said that 100 years ago Laennec of Paris insisted on the large personal element there is in the prognosis of pneumonia. Adding to the difference of season and of place, circumstances and age made great difference in the mortality from the disease. These are abiding truths even down to our own day. The farther advanced the age the worse is the prognosis, but yet comparatively young people die not infrequently, especially in hospitals. During the last five years, the statistics of pneumonia at the German Hospital in Philadelphia, have not been satisfactory. This has led to a careful review of their methods of treatment.

Specifics for Pneumonia.—Dr. Wilson said that many drugs were recommended as specifics

in pneumonia, but none of them really act as such. Some years ago Petruschky attracted attention by announcing that in 1,100 cases of pneumonia, treated by large doses of digitalis, he had had but a little over two per cent. of deaths. His cases, however, occurred among young soldiers with whom the prognosis was naturally good. More recently Aufrecht has found that quinine seems to reduce the mortality from pneumonia. Where the mortality has been from 10 to 25 per cent., it was reduced to less than 8 per cent., and this immediately after a year in which the mortality had been 24 per cent. It is doubtful, however, if there is any specific for pneumonia and the apparent improvement in statistics is really due to the different character of the disease in different years and in different classes of patients. At the German Hospital in Philadelphia they employed antipneumococcus serum in some 40 cases but their mortality was 28 per cent. Hydrotherapy also failed to benefit patients. Dr. Wilson does not believe in the use of veratrum viride, or aconite, to abort pneumonia. There are those who claim good results, but it must be remembered that a century ago venesection seemed to most doctors to produce this effect.

Present Treatment.—At the German Hospital they now employ expectant treatment. Patients are given milk and light gruels or broths with junket, if they want it. Patients are allowed water whenever they wish it, but not more than 2 ounces at a time. They are sponged night and morning, the temperature of the water being according to patient's choice. If the temperature reaches 104° F. a cold sponge is given. Flat icebags are placed on the chest to relieve pain and thus patients are often made very comfortable. About 4 to 6 ounces of alcohol are given in the 24 hours and even more to patients who are accustomed to it. Calomel is given when the case first comes if there has not been free purgation. As a routine treatment, Dover's powder, 2 to 3 grains, every three hours, is given just to the point of drowsiness. Expectorants are rarely given. Occasionally aromatic spirits of ammonia or ammonium carbonate are employed. Nitroglycerine is given for a laboring right ventricle. For dyspnea, oxygen freely mixed with air is employed. For nervous symptoms the Dover's powder is increased and an icebag placed on the head. In severe cases cold is applied to the head and neck. No poultices or jackets are worn. Meat is given as soon as the patient desires it in convalescence, but he is not allowed to get out of bed until satisfactory improvement has taken place.

In discussion Dr. S. B. Ward of Albany said that icebags should not be used if they make the patient uncomfortable. Opiates do good by reassuring the patient. In his own experience Dr. Ward has found creosote carbonate of service, although it is not given if it produces indigestion. There is more danger of overfeeding than of underfeeding in pneumonia. Heart failure is the great cause of death. Hence digitalis should be employed early in the case and it is undoubtedly for this reason that it has obtained its recent reputation.

Fresh Air in Pneumonia.—Dr. Hunter of Toronto said that at the Western Hospital in that city some years ago large tents were erected in the hospital yards for the open air treatment of pulmonary cases. In these, pneumonia cases particularly, do very well. All acute pulmonary diseases are relieved by this open air treatment. If Dr. Hunter were to fall sick with pneumonia he would prefer to be treated under the trees in the park, with a piece of canvas to cover him at night, than in the best appointed hospital in the world.

In closing the discussion Dr. J. C. Wilson said that fresh air is undoubtedly a great desideratum in pneumonia. Military men affected with the disease and treated in tents do very well. Pneumonia is not an uncommon affection in lumber camps. During his autumn vacations Dr. Wilson has had an opportunity to convince himself that pneumonia is not as fatal in the camps as it is in hospital experience.

Mastoiditis.—Dr. T. H. Halstead of Syracuse said that it would be much better if the middle ear were considered as an accessory sinus of the naso-pharynx and the condition of the throat constantly kept in mind whenever there seemed danger of middle ear disease. The formation of pus in the middle ear is even more common than has been thought. In 30 cases of meningitis in children in Munich, although there had been no sign of middle ear disease, the ears were carefully examined at autopsy and in every case were found to contain pus. The pathognomonic symptom of mastoiditis usually given namely the red and tender mastoid process, is really a late symptom in the affection. The disease exists long before this. As a rule, free incision of the drum with free purgation will benefit the acute stage of mastoid disease if employed in time. Morphine should never be given because it masks the symptoms. Ice should be employed during the first forty hours and if it does not afford relief by this time its continued use will only increase the death of bone. When the ear discharges freely, boric acid insufflations should not be used as they retain the secretion.

Antecedents of Mammary Cancer.—Dr. B. Farquhar Curtis of New York said that there are two forms of mammary affections that are of interest either because they arouse in the patient the suspicion of cancer or may precede it. The adenomatous overgrowth in the breast is especially liable to cause discomfort to the patient. Not that there is actual pain, but the patients fear any hardness in the breast. Adenomatous swelling of the breast may cause involvement of the glands. These adenomata may become malignant. Often they are quite hard. As a practical rule Dr. Curtis insists that any of these

tumors that become indurated should be removed. If they occupy less than one-fourth of the breast he removes simply the tumor. Where more than one-fourth would have to be removed in order to cut well wide of the tumor the whole gland should be sacrificed and the axillary glands removed, because these are often found to give pain, and show cancer nodules at times when the breast tumor does not seem to contain them. Adenomata of the breast sometimes seem to disappear of themselves. This form of resolution, however, can not be depended on. Even when the tumor is small, the operator should obtain the patient's consent for the removal of the whole breast, if during the operation there should seem to be any good reason for it. To depend on retraction of the nipple, enlargement of the glands and adhesion of the skin is to invite fatal diffusion of the cancer element before removal. When small tumors are removed they should be submitted to microscopical examination in order to determine if they contain any cancer elements.

Ligation of the Aorta.—Dr. Robert T. Morris of New York said that the aorta has now been ligated some fourteen times. Thus far patients have succumbed, though not immediately. Surely the time is now ripe for successful ligation of the aorta. Of the ten cases done before the days of antisepsis all the patients perished within a short time after the operation. Of the four performed since, Keen's patient lived 48 days, one of the others 29 days. Morris' patient lived for 3 days and then seemed to be doing very well except for a gangrenous condition of the intestines which caused death. Dr. Morris' patient was a young woman of twenty-four years, who developed aneurism of the abdominal aorta. Owing to the pain the condition was considered at one hospital to be a pleuro-pneumonia, and at another an acute gastritis. As the aneurism grew larger the diagnosis became easy because of the immense expansile heaving motions of the abdomen. The aorta was ligated two inches below the aneurism, by a temporary ligature. After twenty hours clotting took place in the aneurism, twenty-seven hours after its fixation the ligature on the aorta was removed. The patient at once began to feel better and asked for food. The pulsation in the femoral arteries which had been completely stopped began again and continued normally. Unfortunately the patient died on the third day from gangrene of the intestines.

MEDICAL PROGRESS.

Removal of Tonsils.—There is a great difference of opinion in regard to the indications which demand amygdalotomy for the results, especially in the adult, are frequently not all satisfactory R. LEVY (*N. Y. Med. Jour.*, Oct. 12, 1901) believes that where there is simple hypertrophy or a diseased condition of the follicles without hypertrophy nothing short of complete removal will assure complete cure, and that this should always be done. The best method in adults is by the glavano-caustic snare, for, by this means, secondary hemorrhage is very unlikely. Complete dissection is sometimes necessary and this may be done by the galvanocaustic electrodes. Simple amygdalotomy is usually sufficient and has many advantages in children.

Respiratory Failure in the Newly-Born.—Two cases of this kind reported by IRVING M. SNOW (*Archives of Pediatrics*, Oct., 1901) showed intense exaggeration of the anal and pharyngeal reflexes, frequent convulsions which seemed closely associated with the respiratory pause, and frequent stoppage of respiration with intense cyanosis and no spontaneous effort at natural breathing. Life was sustained in one case by oxygen and artificial respiration, and if the latter were suspended, in from five to fifteen minutes the breathing became superficial, and finally stopped. Whisky and chloral had been given hypodermically, as the spasms were frequent. The condition of exhaustion and malnutrition being extreme, a soft catheter was introduced into the stomach and two drams of breast milk injected with good effect. The acute symptoms when life was sustained by artificial respiration and oxygen lasted 19 hours, and the child was all right again twenty-six hours after the onset. The other child died after the apnea and opisthotonus had lasted fourteen and a half hours. The writer believes that the attacks were due to pressure on the medulla, the rapid clearing up in one indicating congestion, or slight edema. The success in one case shows the value of persistence in treatment for many hours.

Tincture of Iodine in Acute Amygdalitis.—The intense pain and swelling which accompanies acute amygdalitis frequently baffles the skill of the physician. S. FLOERSHEIM (*N. Y. Med. Jour.*, Oct. 5, 1901) has found after a wide experience that astonishing results may frequently be had by the direct application of the tincture of iodine. A camels'-hair brush is saturated with iodine and rapidly brushed over the inflamed area. The burning is intense, but if it should persist after two minutes a gargle of warm water will give relief. The pain is usually temporary and a second application should then be made in about three or four minutes after the first application. The results are usually marvelous. When the drug has been applied early an apparently intense amygdalitis may be seemingly aborted. In suppurating cases, the pain and swelling are much relieved by this mode of treatment and the rupture of the abscess is apparently hastened.

GIANT SACROCOCCYGEAL TUMORS. AN ACCOUNT OF ONE WHICH PURSUED AN ATROPHIC COURSE.[1]

BY CHARLES A. POWERS, M.D.,

OF DENVER, COLO.;

PROFESSOR OF SURGERY IN THE UNIVERSITY OF DENVER.

IN October, 1897, there came under my observation, through the courtesy of Dr. P. V. Carlin, a male child of three months who presented an unusual growth in the coccygeal region. The tumor was congenital and at birth was said to have been practically of the proportional size and shape which it was when I saw it and to have presented the same general characteristics. The child was mature at birth, at which time the parents were told that it would probably die. The only attention which the mass received was ordinary cleanliness. The child thrived and at three months of age was quite as strong and as well nourished as babies of that age usually are; it had not been ill.

Examination of the child when first seen revealed a very large growth occupying the sacrococcygeal region, extending laterally to the buttocks and forward in front of the anus. The growth encroached upon the left buttock rather more than upon the right, reaching well to the gluteal fold on the left side. It was irregularly

Fig. 1. Congenital sacrococcygeal tumor; child three months old.

ball-shaped; the entire mass was as large as the head of a child six years old. The tumor measured seventeen inches in circumference. The general consistency was soft. Below and in front it was markedly cystic and fluctuating, while above and laterally it was firm and in places nodular. The firmer portion seemed attached to deep structures and these more solid parts were thrown

Fig. 2. The same.

into large irregular folds with deep creases between them. The skin over the tumor was normal above and at the sides, but very thin and of a bluish-red over the cystic parts. Large veins crossed the latter portions. The skin was freely movable over the fluid portion of the tumor, but tightly attached in the crevices above mentioned. The cystic portion swayed with the movements of the child. Palpation of this gave the impression of one or more large cysts and many small ones with here and there firm portions of tissue. Deep palpation failed to reveal a gap in the bony structures. Digital examination of the rectum showed nothing abnormal. The bowels had been regular and the movements natural; there had been no abnormality of micturition. When the child cried the upper lateral parts of the tumor were moved by the gluteal muscles, but the tension of the mass itself was not changed. There was neither paralysis nor anesthesia of the lower extremities. The size, shape and location of the tumor are very well shown in Fig. 1 and Fig. 2.

Removal of the mass was not advised; the tumor was too large and the baby too young. Aspiration of the fluid contents was suggested, but the parents did not take kindly to the thought and it was not urged. The mother was asked to keep it very clean, to wash it with dilute alcohol and dust it with a simple dusting powder, protecting it well with soft clothing. She gave it the best of care.

Three months later the tumor was in about the same condition; there had been no appreciable

[1] Read before the American Surgical Association, 1901.

change. Six months after this, or when the child was about one year old, the fluid portions of the tumor seemed to be less prominent; the tumor itself had rather less of a ball shape, and was beginning to get flat.

Fig. 3. The same at three and a half years of age.

The child was seen at intervals of two or three months. The tumor underwent progressive contraction; the skin over it never broke; it was never ulcerated. The boy had the usual diseases of childhood, measles, whooping-cough, diphtheria, etc., but his physician said that he came through them all without accident. He waxed strong and hearty. "He is the strongest of my six children," said the mother.

Fig. 4. The same.

Figs. 3, 4, 5 and 6 show the condition in March, 1901, the child then being three years and nine months of age. At this time the tumor was well flattened out, circular in outline, extending to the gluteal fold on the left side, but not quite so far as this on the right side; anteriorly it went to the anal margin in the middle line and in front of the anus on the right side. Above it was limited by the middle of the sacrum. Its diameter was five inches; in size it was somewhat larger than a man's fist, well flattened out. The skin over it seemed rather thick; it was movable in places. Here and there it was thrown into deep folds and at these folds the skin was tightly adherent. At

Fig. 5. The same.

the right extremity a hard nodule an inch and a quarter long and one-half inch wide was plainly felt. This nodule or lump could be bent slightly on itself, it moved freely on the deep parts, but the skin over it was attached. The entire mass was movable. As the child lay on its mother's lap and kicked its legs the upper lateral parts of the tumor moved, the skin over it being thrown into deeper folds. The mass was nowhere tender or inflamed; it seemed to be solid throughout. Rectal examination was negative.

This boy is well developed, strong and healthy.

Fig. 6. The same. Figs. 3, 4, 5 and 6 are to be compared with Figs. 1 and 2, in order to show the spontaneous contracture which the tumor has undergone.

He plays about like other youngsters of his age and has no symptoms whatever referable to the lower extremities. He runs about, lies on his back and sits like other children. He does not favor this portion of his body in any way; in a word, except for its mere presence this tumor gives no general or local symptoms. The boy never seems conscious of it.

Some variety of congenital malformation of the sacrococcygeal region is very common. That

most often seen is the simple dimple or groove, the so-called fovea coccygea. Beyond this we have the true epidermoid fistula or pilo-nidal sinus, and a step further brings the true dermoid. In this class also may be placed sacculation of the cord connected with vertebral fissures, spina bifida occulta. All of the foregoing are of single germinal formation. The more complex growths are of double germinal substratum—complete or incomplete double formations, and parasitic cystic mixed tumors (teratomata-embryoid tumors). I believe that the case here related belongs to the last class, and, while it lacks histological confirmation, one may reason by analogy from similar growths which have been pathologically examined.

These sacrococcygeal teratomata present the greatest diversities of tissue. They form a class of tumors by themselves. They are generally mixed, and in addition to the structure of dermoids they may and often do present cysts lined with ciliated, flat or columnar epithelium, muscle fiber, nerve tissue, intestinal remnants, bone and cartilage. Rindfleisch names such a growth a "histological potpourri." The region itself presents as much diversity of structure as does that of the face.

Stolper[1] has recently given the subject careful attention. He approaches it almost entirely from the genetic or histological standpoint. He found that many cases of spina bifida are multilocular and can be told from teratoid tumors only by microscopical study; combination of both forms may occur. Stolper affirms that it has not yet been proven that the remnant of the medullary canal, a persistent coccygeal vertebra, the neuroenteric duct, or Luschka's gland may be the starting-point of such a growth though the possibility of this is not denied. One thing is certain and that is that teratoid tumors of the sacrococcygeal region unanimously show components from all three of the germinal layers. Variations in the mode of growth are responsible for the great disparity in the microscopic appearances. The manifold coarse and fine structure, the indications of so many different organs, the cyst formation, the differences in the epithelium in one and the same cyst are readily explained by the assumption of double germinal substrata.

Fig. 7 is from a photograph of a remarkable case which was under Stolper's observation,[2] a giant sacrococcygeal tumor in a child five months of age.

"The tumor is one-half as large as the child itself. It is irregularly ball-shaped, there are muscular movements in it when the child cries. The skin is movable and normal. Extirpation under chloroform. But little loss of blood. Broad pedicle springing from dorsal surface of sacrum and coccyx. Coccyx itself not involved in the tumor. Duration of operation one hour. Death a few hours later. No autopsy, therefore no data in addition to those afforded by the operation.

"*Pathological Report.*—After contents (1,100 c.cm.) of a large cyst had flowed out the tumor weighed three kilos. The lower part of it was cystic. The upper, solid portion, consisted in part of fat and muscle fiber, in part of nerve tissue. There was much intestinal mucous membrane in the cyst walls.

"We have here a giant growth consisting in part of large and small cysts, in part of solid tissue, the latter containing in the greatest irregularity of distribution smooth and striped muscle fiber, fatty tissue, connective tissue, glandular tissue having the structure of the salivary glands, cysts with flat and columnar epithelium, cartilage, nerve tissue, etc. The nerve tissue has but few ganglion cells but is rich in masses of gliomatous tissue."

Stolper's observations seem to be confirmed by a recent case reported by Hagen-Torn.[3] This concerns a very interesting case of congenital sacral tumor which, in addition to many forms of

Fig. 7.

intestinal tissue, contained sarcomatous and myxo-sarcomatous degeneration. He considers it a malignant degeneration of a sarcomatous nature which had its origin in a small, double germinal malformation.

Phocas of Lille[4] reports two cases, one a five-year-old child presenting a tumor 12 centimeters in breadth by 11 centimeters in thickness, and a second child of twenty-two months with a tumor 43 centimeters in circumference, the pedicle of which measured 9 centimeters in breadth and 25 centimeters in circumference. Both tumors were markedly cystic and both showed the most diverse tissue constituents. Extirpation was successful in both cases. Phocas advises delay in these cases until the children reach such age as to enable them to withstand operation. When the tumors are very large it may be better to extirpate them in multiple sittings.

Broca and Cazin[5] made careful examination of two specimens, one from a child of six weeks, the other from a child of four years. Both operations were successful and both specimens showed sections of intestine having about the diameter of a goose-quill, laid down in the midst of large

masses of small cysts. The microscopical evidences of the intestine were characteristic. The cysts were lined with ciliated epithelium. The authors believe the tumors to have sprung from the neuro-enteric canal.

Calbe[6] discusses at length six teratogenetic tumors and arrives at the conclusion that twin monstrosities and congenital sacrococcygeal tumors belong practically in the same class, and that microscopical investigation will show all possible stages between the simplest and the most complicated growths.

Nasse[7] reports on five congenital coccygeal tumors each of which had a ventral seat. Some of these operations were exceedingly difficult; the cysts reached so high in the pelvis that they could not be extirpated *in toto*. The most diverse tissues were found in these tumors—connective tissue, bone, cartilage, flat muscle fiber, conglomerate glands and mucous cysts which showed in

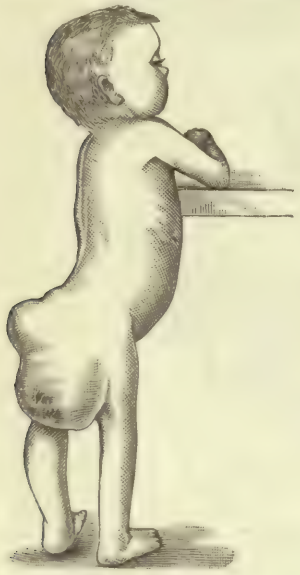

FIG. 8.

FIG. 9.

part ciliated epithelium and in places a transition from squamous to cylindrical epithelium. One of these tumors was a simple dermoid; the author assumes that the other four arose from the post-anal remains of the intestinal tract. Nasse says that while teratomata of dorsal growth often contain nerve tissue those ventrally situated are generally cystic.

Perman of Stockholm[8] reports an operation on a five-months-old child who had a cystic sacrococcygeal teratoma the size of a baby's head. The mass was limited below by the gluteal fold; on the right side it reached to the trochanter major and it stretched some two inches across the middle line in the sacral region. The skin over it was very thin and movable. On operation several large cysts and many small ones were found, together with masses of gliomatous tissue. Large nerve fibers could not be demonstrated. Here and there cubical and cylindrical epithelium. The coccyx was pressed somewhat to the left side, but no gap in the spinal column could be discovered. The child recovered. From the presence of the large amount of gliomatous tissue Perman assumes that the structure came from the same embryonal tissue as the brain and spinal cord.

Ritschl[9] removed a tumor the size of child's head from the sacral region. The mass was found to be made up of many different tissues, in part cystic and in part solid "characteristic fetal rudiments."

Other and similar observations might be cited, but I believe that the foregoing tend to strengthen the assumption that the case which I report may properly be placed in the class of teratomata and embryoid growths. Its appearance at birth and a few months thereafter, its partly cystic and partly solid nature, its size and seat all place it in line with the cases histologically examined by Stolper and others. However instructive it might be to add the pathological report, I am quite content to have had the tumor undergo spontaneous contraction. The age, size and strength of the child, the absence of local pain, tenderness and ulceration, the progressive shrinkage of the tumor itself, all lead me to hope that Nature may have cured the condition. It is possible that further growth may take place, that malignant degeneration may ensue as time goes by. I am unable to obtain record of any case in which a similar tumor has pursued the course of this.

FOUR CASES OF TUMORS.[1]

BY JAMES E. NEWCOMB, M.D.,
OF NEW YORK;
INSTRUCTOR IN LARYNGOLOGY IN THE CORNELL UNIVERSITY MEDICAL COLLEGE.

DURING the past year four interesting cases of tumors have come under the writer's observation and are deemed by him worthy of record.

Case I.—Osteosarcoma of Inferior Turbinate: A. B., colored, male, aged forty-one years, came to the writer's clinic in the Out-Patient Department of Roosevelt Hospital, September 25, 1900. He stated that for some four months he had had an obstruction of the right naris, constant and increasing. There had been neither pain nor hemorrhage. At times there had been a moderate post-nasal discharge. The patient was stout and well built, but somewhat asthmatic and emphysematous.

Examination of the right naris revealed an apparently bony adhesion between the inferior turbinate and the septum, beginning about three-quarters of an inch from the vestibule and running backward for half an inch. The obstruc-

[1] Read before the American Laryngological Association, New Haven, Conn.

tion was removed by trephining and there was no unusual hemorrhage. Healing promptly occurred and for some time the patient could breathe easily through that side. In a few weeks, however, he returned with the same symptoms as originally noted and examination showed a reformation of the bony mass which was larger than

Fig. 1. Osteosarcoma of Inferior Turbinate.

before. With the trephine a considerable core of tissue was removed and submitted to Dr. Jonathan Wright, of whose courtesy in this and the following cases I would here make grateful acknowledgment. His report was as follows: "The subepithelial tissue of the mucosa is entirely made up of spindle-celled fibrous connective tissue with newly-formed capillaries running through it. The tendency to crescent shapes in the arrangement of the cells presents the familiar picture of a spindle-celled fibrosarcoma. In places there is a proliferation of cells which apparently spring from the endothelium. In the deeper layers (Fig. 1) bony tissue of apparently new formation may be seen with a lining of osteoblasts (Fig. 2) along the edges of the scattered areas. The sarcoma formation fills the interstices of the bony tissue and is quite as characteristic there as elsewhere. In places a double row of osteoblasts may be seen which have apparently extruded the lime salts between the rows, and this has not yet assumed the formation of bone and it appears more or less amorphous. There can, therefore, be no doubt in this case that we have to do with a true osteosarcoma and not with a sarcoma secondarily involving subjacent bone."

In view of the nature of the growth the patient was urged to enter the hospital with reference to a more radical intervention than was possible in the Out-Patient Department. This he agreed to do, but failed to return.

Case II.—True Papilloma of the Nasal Septum: J. T., merchant, American, aged fifty-five years, was seen in consultation with Dr. F. M. Crandall for severe epistaxis. The nasal septum was strongly bulged to the right and presented on its convexity a large erosion from which the blood came. Pure silver nitrate was applied and the bleeding was checked. During the systematic examination of the patient I discovered a small cauliflower-like mass on the left side of the septum at its top just at the junction with the ala. It had given no symptoms and the patient was unaware of its existence. It was removed without incident and proved to be a true papilloma (Fig. 3).

Dr. Wright's report was as follows: "The growth is chiefly a proliferation of epithelial cells which partake somewhat of the characters of both the pavement and columnar varieties. It is supported both on the surface and dipping down into the tissue by a delicate network of connective-tissue digitations with a central blood-vessel, the whole presenting a typical picture of the so-called papilloma or fibroma papillare."

The question of nasal papilloma has been thoroughly discussed at various meetings of this Association and the ground need not be re-traversed here. The case is reported on account of the rarity of true nasal papilloma. Arrowsmith of Brooklyn reported in 1897[1] a case of this nature and stated that he had been able to find in literature up to that time but 29 instances of true papilloma of the nose and that in some cases of the series the diagnosis was by no means certain. Since the date of Arrowsmith's paper I have been able to find records of nine additional cases, as follows: Borgoni, Gior. Ital. di Lar., No. 1, 1899, p. 1; Yearsley, Jour. Laryngol., Vol. xiii., 1898, p. 303; Douglass, N. Y. Med. Jour., Jan. 7, 1899, p. 6; D'Aguano, Arch. Ital. di Otol., Vol. iv., 1896, p. 99; Reale, Arch. Ital. di Laringol., Vol. xx., 1900, p. 57; McKinney, N. Y. Med. Jour.,

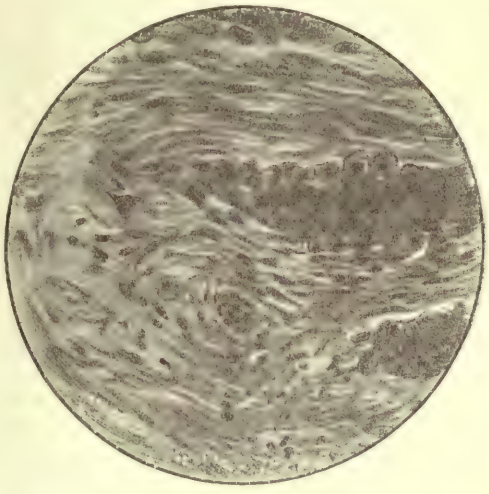

Fig. 2. The Same as Fig. 1, High Power.

Mar. 4, 1899, p. 290; Williams, Diseases of the Nose and Throat, 1895 (two cases); Noquet, Rev. hebd. de Laryngol., Sept. 18, 1897, p. 1121.

Case III.—Sarcoma of Branchial Cleft: G. A. D., American, carpenter, aged sixty-five years, came to the Out-Patient Department of Roosevelt Hospital March 7, 1901, complaining of a "swell-

[1] Laryngoscope, Nov., 1897, page 283.

ing in the throat." The notes of the case are taken from the records of the First Surgical Division of the Hospital, service of Dr. Robert F. Weir, to which the patient was referred for operation. The patient was a moderate user of alcohol, had had lumbago and some catarrh of the throat, but

Fig. 3. Fibroma Papillare of Nose.

had been otherwise well until two years before coming under observation. There was no history of syphilis.

Two years ago he noticed a swelling on the right side of the palate and a soreness in the gums of the same side. The swelling gradually increased, with a continuance of the soreness, until one year ago when it was lanced and a fluid, of thin consistency and clear in hue, escaped. Since that time he has had no pain. After the lancing, the swelling gradually increased again for six months when it was again lanced, and this operation has been repeated several times. No change in the character of the fluid was noted. The swelling began near the middle line of the soft palate and never entirely disappeared after incision, but gradually spread to the side of the mouth and somewhat backward and forward. At first it was supposed by the patient's physician to be some sort of quinsy. Speech gradually became muffled and indistinct and there was some limitation in the movement of the jaws. No lumps were noted on the side of the neck. The appetite had been poor for two years and he had lost some ten pounds in weight. There were dyspnea and palpitation on exertion. The heart was normal, but the lungs were somewhat emphysematous.

Examination of the throat revealed the soft palate pushed well over toward the left by a tumor occupying the right side extending from opposite the last molar tooth upward and inward to beyond the median line, downward to the floor of the mouth and backward into the pharynx. It was tense, elastic and smooth with one or two harder spots on its surface. It could also be felt just behind the angle of the jaw and fluctuation was transmitted from pressure on the inside to the finger on the outside of the mouth. No enlarged glands were discovered either in the neck or on the floor of the mouth. There was slight tenderness over the cornu of the hyoid bone on the right side.

On March 16th Dr. Weir operated as follows: An incision was made from half an inch below the lobe of the right ear down along the middle of the sternocleidomastoid muscle to the level of the thyroid cartilage. A second incision was made from the margin of the jaw one-half inch from the median line to meet the first opposite the hyoid bone, through skin, fascia and platysma, until the muscular planes were reached. The digastric and stylohyoid muscles were exposed. The tumor was felt above the muscles, running up beneath the jaw and the tissues were incised down on to it. The mass was of a bluish color and felt cystic. Blunt dissection with the finger was carried all around it and the tissues freed from it. It was found to reach upward almost to the base of the skull. It was carefully separated from the muscular structures of the pharynx and soft palate, caution being taken not to break through the buccal mucosa to which the sac-wall was attached. In this way the tumor was shelled out. It was about the size of a mandarin orange and on one portion of the wall was a solid mass, in size and shape resembling a tonsil. In the process of removal a portion of the sac-wall was punctured and a bloody fluid escaped. The progress of the case toward recovery was uneventful. The mass removed was sent to the laboratory of the Columbia University Medical School and the report returned read as follows: "Telangiectatic sarcoma of the branchial cleft with hyaline degeneration; lymph-nodes hyperplastic; no tonsillar tissue."

My thanks are due Dr. Weir for courtesies rendered in connection with the case.

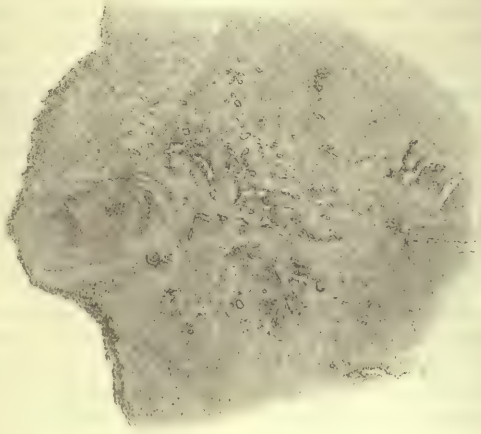

Fig. 4. Angiofibroma of Nose.

Case IV.—Angiofibroma of the Nose: J. K., Irish-American, aged twenty years, was referred to me by Dr. F. R. Oastler, April 29, 1901. His family and previous history contained nothing bearing on his present condition. For seven

months he had complained of nasal stoppage alternating from side to side, but finally settling and becoming permanent on the left side. Examination through the nasal speculum showed what was apparently an ordinary nasal polyp hanging from the middle turbinate. The post-nasal mirror, however, revealed a mass in the nasopharynx reaching back from the choanæ, but apparently blocking only the left. On attempted removal with the cold wire of the mass visible anteriorly, the growth proved to be so hard that the wire would not cut through it and pulled out of the snare. On a second attempt the wire actually broke. The bleeding was very free, but was checked with gauze packing. The next day with the same snare a piece was removed and sent to Dr. Wright for examination. On this occasion the bleeding was excessive and was checked with difficulty. The patient has been advised to submit to radical intervention, but thus far has refused his consent.

The report on the growth was as follows: "An irregular fragment of tissue hardened in alcohol of gradually increased strength, mounted in celloidin, cut and stained with hematoxylin-eosin, shows in some areas a structure at first glance resembling an ordinary edematous polyp. There is, however, even in these places much more fibrous tissue than usual, but it has undergone a hyaloid change, the outlines of the fibers being broken, irregular, strongly refractive of light and taking the eosin stain deeply. In the field from which the drawing (see Fig. 4) is taken, there is a dense ovoid fibrous nodule, plainly discernible. Throughout are to be seen numerous vascular channels, enough to warrant the term "angiomatous." They are lined with a layer of endothelial cells, the other part of the walls of the vessels being the fibrous tissue itself. Under a higher power many of the nuclei of these endothelia are seen to be swollen and projecting into the lumen. In the areas where the fibrous tissue is broken, there are large numbers of mononuclear round cells. The epithelium of the surface is of the modified columnar variety without cilia. No glands are to be seen and the new Weigert stain does not reveal any elastic fibers. There are no evidences of malignancy, but from the history I should suspect that the piece removed is not characteristic of the whole. Whatever else the rest of the growth may show, I should expect it to be vascular and fibrous. I see nothing in the clinical history to warrant any other diagnosis than the findings of the histological examination, *i. e.*, an angiomatous fibroma."

Such cases are extremely rare. The one in question has come under observation so recently that I have not had time to look up the literature of the subject. Dr. Wright informs me that he has knowledge of only one other similar case, namely, that submitted to him by Dr. C. H. Knight and which is published in the Manhattan Hospital Reports for January, 1895. In this latter case the growth was small and movable, being attached to the posterior end of the middle turbinate. It was covered with columnar epithelium and was made up exclusively of homogeneous bundles of curling elastic fibers.

The exact origin of the growth in my own case, I have thus far been unable to determine. It apparently springs from the general region of the middle turbinate, but more definitely than this, I cannot say. A physician who saw the case before I did reported that the post-nasal prolongation pulsated. I could not determine this at the times of my examination.

118 West 69th Street.

BIOPSY—THE HISTOLOGICAL DIAGNOSIS OF DERMATOSES AND TUMORS OF THE SKIN OF DOUBTFUL CHARACTER.

BY JEAN DARIER, M.D.,
OF PARIS, FRANCE.

It would be unjust to say that progress has not been made in the last twenty years in exact knowledge of many cutaneous diseases and tumors. Nevertheless in every dermatological clinic and even in active private practice scarcely a month passes without presenting a dermatosis or a neoplasm, the nature of which it is impossible to diagnose with certainty. I do not here refer to the doubts of the practitioner little versed in dermatology; I have in mind the learned and experienced dermatologist, commanding all ordinary or necessary means of information, who may easily find himself face to face with affections which cannot be diagnosed with all the resources of the ordinary clinic.

What can be done in such a case? The lesion has been examined with the greatest care, the entire body has been explored, the patient's previous history and the evolution of the disease have been investigated as far as possible, competent consultants may even have been called in, and doubt remains. This doubt may have the most serious consequences. Suppose, for example, an ulcerative lesion of the nose or lips which might be syphilitic, tuberculous, cancerous or actinomycotic. According to the nature of the lesion it could be cured by specific treatment, or it might demand cautery or scarification, or might call for complete and rapid destruction or ablation. In the face of a spreading lesion shall experimental treatment be tried at the risk of losing valuable time? Or, on the other hand, shall the patient be submitted to a radical disfiguring operation without absolute necessity? In doubtful cases of this nature there is an "invaluable resource which will solve the problem rapidly, almost with absolute certainty, and without discomfort or danger to the patient; I refer to biopsy.

The name "biopsy," coined by Besnier, is most happily chosen. Biopsy is a sort of "autopsy on the living;" it is the excision of an eruptive lesion or a fragment of tumor for the purpose of establishing the diagnostic histology of a malady. It is to take not a scale, a crust or a hair, but a complete eruptive element and thus to add to the

symptomatology of a disease the notion of its pathological anatomy. One can well understand the value of resort to such a means of investigation when the insufficiency or vagueness of the objective and rational signs leave the clinical diagnosis in a state of doubt. Moreover, biopsy makes it possible to discover and describe in complete form a certain number of new diseases which to-day are entitled to a legitimate place in dermatological nosography. Hitherto, biopsy has only been mentioned incidentally and apologetically, apropos of some rare and curious affection, as an extreme resort where all other means of diagnosis fail. It deserves a place different from that which has been accorded it.

The question whether one is justified in removing a shred of skin from a patient is best answered by comparing the advantages of the practice with its disadvantages. The advantage of biopsy is that it furnishes a means of diagnosis, and upon diagnosis treatment depends. Its disadvantages may be briefly enumerated and disposed of, as follows:

1. *The Apprehension of the Patient.*—This is easily obviated by reasoning presented with tact. In more than six hundred proposals of biopsy I have met with only two or three refusals.

2. *Pain of the Operation.*—I shall point out farther along how this can be obviated; the same will be done concerning hemorrhage, which, while disconcerting at times, never is dangerous.

3. *Infection.*—This is easily avoided by strict asepsis. The cicatrix does not seriously enter into consideration if biopsy is resorted to only in grave cases. It may be said that the real obstacle to the general adoption of the biopsy resides in the demands it makes for time and for expertness in histological technic. In any event the physician who is insufficiently equipped or too much occupied to make the necessary histological examination can always submit the specimen obtained to a histologist.

Method of Operation.—The choice of the portion of the tumor or ulcer to be excised is a delicate matter, demanding a clear idea of what one is seeking; on this choice depends the ultimate success of the operation. General instructions can scarcely be given on this point. In the case of an eruptive element, however, it is desirable ordinarily to choose the most recent among the most typical spots found; in the case of an ulcer, the part excised should include the border with a small portion of the base; in the case of a tumor the most characteristic area should be selected.

The dimensions of the fragment to be removed vary according to the case; as a rule, a piece as large as a hemp-seed or a lentil suffices. The process of removal must insure a piece which is neither crushed nor torn. It is inadvisable to use the sharp curette or the scissors because these instruments compress and destroy delicate tissue. Methodical surgical procedure, with incisions by the bistoury under aseptic precautions, with local or general anesthesia, hemostasis and continuous sutures, is applicable only to cases where hairy skin is removed, or where extensive sections are to be made. As a rule this procedure is too long, too complicated and too alarming. The following method is simple and rapid and gives excellent results in an immense majority of cases.

The instruments required are a von Graefe knife, anatomical forceps, histological scissors, either straight or curved, with blunt ends; these are sterilized. The operator's hands are washed; the field is disinfected. If the patient is timorous anesthesia is obtained by means of an ethyl-chloride spray; a disadvantage of this method is that when the tissues are congealed it becomes difficult to distinguish the element chosen for incision. To overcome this obstacle the part may be previously marked with ink; another method is to postpone the operation until the moment when the blanching of the skin disappears—anesthesia is not complete at this moment, but there remains a sort of stupefaction of sensibility.

Subcutaneous injections of cocaine must be rejected absolutely in this operation because of the local edema which they produce, the interstitial hemorrhage provoked by the needle, and the alteration in the tissues which results from contact with an aqueous liquid. But in ulcerations and erosions of mucous membranes one may apply locally a cotton sponge soaked in solution of cocaine, 1 in 10. Practically, local anesthesia may generally be dispensed with. It is well to remember that the best analgesic is an exceedingly sharp instrument.

In making the incision the operator picks up the selected part with the thumb and forefinger of the left hand; this fold is transfixed at the desired depth by the Graefe knife, which is plunged beneath the portion destined for excision; the knife now cuts a flap which includes the desired piece. The flap is picked up with the forceps, is detached at the base by the scissors, and the section is immediately plunged in the fixing fluid.

Hemorrhage usually is insignificant, but is somewhat more abundant where an anesthetic has been employed. A good local hemostatic is a fine powder of juniper-wood, sterilized by heat and impregnated with vapor of creosote. This is superior to antipyrine and more practical than gelatin, which must be softened by heat. Sutures may be resorted to after deep and wide excision of healthy tissue—a rare condition in biopsy. A simple dressing of iodoform gauze held with collodion, suffices.

Histological Technic.—Sufficient instructions on this point cannot be given within the limits of this article. Those familiar with laboratory methods of fixation, hardening, cutting and staining will know how to apply those methods. The most common mistake is to apply a single method indiscriminately to every case. Reagents should be chosen with reference to the object sought. For example, to use alcohol, paraffin or celloidin in examining a xanthomatous tubercle is to de-

feat one's aim, inasmuch as the fat which ought to be preserved would thus be dissolved.

The excised tissue should at once be immersed in the fixing agent which has been chosen. In most cases preference may be given to alcohol or acetic sublimate. Where alcohol is used it is possible to make a section of the already hard specimen within several hours of the operation; by staining with picrocarmine and mounting in glycerin, a rapid diagnosis may then be made. If doubt remains, there is nothing to prevent the preparation of a second specimen by imbedding in paraffin or celloidin in the usual way.

It is frequently important to make the section exactly perpendicular to the skin, or as nearly so as possible, so as to include the various parts of the tissue. For example, in making a section of the border of an ulcer, the part removed should include healthy skin as well as the border and the floor of the ulcer.

Staining and mounting are the final steps. Staining fluids should be regarded as true microchemical reagents of extremely sensitive character, capable of bringing out certain properties of the tissues and elements on which they act; they should be chosen with reference to the problems which present themselves in each case.

Indications for Biopsy.—Biopsy is indicated whenever the practitioner is face to face with a cutaneous lesion, or an accessible lesion of a mucous membrane, of which definite diagnosis cannot otherwise be made. Clinical diagnosis must naturally be pushed as far as possible first. As the nature of a dermatosis often becomes clear when its special evolution is observed, patients should be kept under observation for some time before resorting to biopsy, except in urgent cases.

With regard to urgency, there are two distinct classes of cases. The first group, in which the indication is absolute and pressing, includes tumors and ulcers of doubtful character which tend to invade surrounding tissues, such as tumors of the tongue, lips or face. Here biopsy is obligatory and indispensable, as it alone can decide whether treatment is to consist of specific medication, topical applications, or surgical intervention. Prognosis often depends on precision and rapidity of diagnosis.

It is entirely otherwise with a second group of cases. For example, in the case of multiple tumors, annoying to the patient, but unquestionably benign, or of a persistent eruption of indeterminate character, the biopsy may be proposed as a means of throwing further light on the case. Without attempting a classification of cases in which biopsy is either obligatory or merely useful, let me try to give an idea, based on my personal experience, of questions which this operation may be expected to solve, and of the relative frequency with which these questions present themselves.

In the front-rank must be placed the diagnosis of epitheliomata; the most common cases are those presenting an ulcerative lesion of the face or of the buccal cavity. The clinician is often uncertain whether he is dealing with an epithelioma, a tuberculous ulcer, a gummatous syphilide, a chancre or a dental ulceration; at times even actinomycosis, farcy or sarcoma must be taken into account. Even when all the probabilities point to cancer, it may be desired to settle all possible doubt before resorting to a mutilating operation.

Superficial and benign epitheliomata are sometimes difficult to distinguish from lupus vulgaris, tuberculosis verrucosa or lupus erythematosis. Often in affections which have been termed "precancerous," such as senile keratoma, xeroderma pigmentosum, leucoplasia, Paget's disease of the nipple, one is uncertain whether the epithelial modification has become epitheliomatous. In all these cases biopsy become absolutely necessary.

The numerous varieties of cutaneous tuberculosis furnish frequent occasion for fruitful resort to biopsy. Vegetating or ulcerative lupus may also become a point of departure for the development of epithelioma. The difficulty of distinguishing certain cases of lupus and of tuberculous ulcer from tertiary syphilis, is classic.

The dermatoses which are grouped in the vague class "tuberculides" almost constantly demand biopsy for the determination of diagnosis. This is true for follicular tuberculides, acne cachecticorum, lichen scrofulosorum, and for tuberculides in the form of disseminate lupus. The recognition of lupus erythematosis is usually easy, but there are doubtful cases.

Syphilis produces lesions so polymorphous and dissimilar as to simulate nearly every variety of tumor, ulcer or dermatosis. Hence there is here a large field where the microscope is at present useless. The syphilitic chancre, the secondary and tertiary lesions have a pathological anatomy which appears more and more pathognomonic the more one studies it closely. In any case their histological differentiation from tuberculomata and tuberculides, from leprosy, mycosis fungoides, various species of sarcoma, is nearly always easy; their differentiation from epitheliomata is truly elementary.

The difficulties of diagnosis between syphilides and epitheliomata are related exclusively to biopsy. It is to biopsy and not to the test of specific treatment that one must address himself in a doubtful case. If mercury administered by mouth or by inunctions to patients suffering from epithelioma is simply useless; if insoluble injections (and notably injections of calomel) appear at the beginning of epithelioma to be capable of diminishing the volume of the tumor, iodides are on the contrary distinctly injurious to such patients, inasmuch as they stimulate the epithelial neoplasm. Hence here as elsewhere diagnosis must *precede* treatment.

Leprosy must be more and more taken into account in doubtful cases, since easy communication has been established with countries where this malady produces its most serious ravages. In the early periods the presence of Hansen's

bacillus may be demanded to make the diagnosis certain. Recent researches have shown that often one can discover this germ in the mucous membrane of the nasal fossæ. If this fails, and if the case presents suspicious tubercles or even macules, it is necessary to resort to biopsy.

Mycosis fungoides is another grave disease in which one should surround his diagnosis with every guarantee of accuracy. The structure of these tumors is characteristic; but biopsy is especially valuable for diagnosis during their early stages, when they present the appearance of eczematous or lichenoid plaques, or of mycotic erythodermia.

Sarcoma and its special varieties, lymphosarcoma, angiosarcoma, fibrosarcoma, often cannot be diagnosed with precision without resort to the microscope. In actinomycosis, farcy and glanders, rhinoscleroma, the pathogenic element is relatively easy to discover; nevertheless biopsy may be here appealed to to furnish an additional diagnostic point.

Cases in which biopsy is optional are those of benign multiple tumors which are depressing because of their number and persistence. If any doubt remains as to the nature of such tumors it is wise to propose biopsy. This group includes nævi, sebaceous adenoma, lipoma, fibroma, myoma, angiokeratoma.

In special cases I have resorted to biopsy for the diagnosis of common dermatoses, which in an immense majority of cases can be differentiated without question by mere clinical examination. Among these are seborrheic eczema, psoriasis, pityriasis rubra pilaris, lichen planus—the latter, especially in atypical forms, may accidentally present problems which histological examination is capable of solving.

To sum up, biopsy is an operation which furnishes an easy and rapid means for establishing or confirming a diagnosis otherwise impossible or doubtful in the case of various dermatoses and cutaneous tumors. It is too often neglected by some, and very rarely employed by others. For this reason I have believed it worth while to recall it to the attention not only of dermatologists but of physicians and surgeons generally.

REPORT OF TWO INTERESTING CASES OF APPENDICITIS.[1]

BY WILLIAM B. YOUNG, A.M., M.D.,

AND

WILLIAM M. JOHNSON, M.D.,

OF BON AIR, TENN.

THE question of when and how to operate in all cases of appendicitis is still an unsettled one, and until it is definitely determined, I suppose papers will be read and discussed at the meetings of almost all medical societies. In point of fact such should be the case, because the more the subject is discussed the nearer we approach the truth.

[1] Read before Upper Cumberland Medical Society.

The two cases I here report proved to be very interesting and just a little puzzling to the members of our County Society, and for this reason I decided to read a report of them before the Upper Cumberland Society.

Case I.—This was a patient of Dr. H. L. Fancher, who has kindly given me the following history:

"Boy, aged four and one-half years. Dr. Fancher was called to see him on June 27, 1900, and found him in bed with a pulse of 130 and a temperature of 103° F., with considerable tympanites. The parents said that he had been sick three or four days and that his bowels had not moved during that time. The child did not complain of pain, but was very nervous, with extreme subsultus tendinum. He was given ½ grain of calomel every hour until 2 grains were given; to be followed next morning with castor oil.

Next day found the patient's condition was unchanged and without a bowel action. Magnesium sulphate was ordered, one dram; to be followed in four hours by an enema, after which the bowels moved and temperature dropped below 100° F., pulse better, and nervous symptoms improved.

After this the fever began to rise gradually, with morning remissions, until on the fifth or six day the temperature was 105° F. and in the evening he had a dry tongue and some tympanites; assuming by this time a typical typhoid condition. About July 10th the boy began to complain of tenderness in right iliac region, and there was suddenly developed a board-like rigidity of muscles on the right side."

On July 15th I saw the case in consultation. On the 16th the boy was improving, it seemed, and we deferred operation. But on the 20th the condition was much worse, there being extreme tenderness on the right side of abdomen and an enlargement about McBurney's point. I advised an immediate operation. Dr. John P. Williams saw the case at this time and agreed with us in regard to the necessity of operating. I operated on July 21st, assisted by Drs. Fancher and Williams, I opened the abdomen near McBurney's point and found a hard agglutinated mass seemingly just over and a little to the right of the promentory of the sacrum. There were bands of adhesions which ran from this mass to the liver, right kidney and to the umbilicus. Just underneath the umbilicus the adhesions were thickened, forming a hard lump about the size of a large marble, which could be distinctly felt before the abdomen was opened. Not being able to find the appendix, locate any pus nor make a clear diagnosis of what we found, and on account of the very weak condition of the little fellow, we decided to simply close the abdominal wound and trust to Nature.

I was confident that the boy would die, but to our surprise the day after the operation the temperature and pulse began to drop. On the eighth day after the operation the stitches were removed, the wound having healed by first intention, and the temperature and pulse were normal.

On August 5th the case was dismissed, the patient being able to sit up. About the fourth day after the operation the child passed (so the father stated) about one-half pint of bloody pus from the bowels, also quite a quantity of thick milky urine for several days. The urine we examined and found that it contained a quantity of pus.

Dr. Fancher and I at first believed the case to be one of typhoid fever. Whether or not the Doctor has changed his opinion I do not know, but after a careful review of the literature of appendicitis, I am now of the opinion that it was an atypical case of appendicitis. At this writing the boy remains sound and well.

Case II.—I. L. Mc., of Spencer, Tenn., a physician, twenty-eight years old. Previous health from childhood good. About October 1, 1900, the doctor began to feel unwell, and for a few weeks was hardly able to attend to his practice. This he attributed to losing sleep from a busy season in his work. His tongue was coated and he suffered from headache. About three weeks after the beginning of his malaise, he began having wandering pains in the abdomen, lasting from one to five minutes. Between the attacks of pain, he would be entirely easy except for a vague feeling of indisposition. This general painful condition of the abdomen lasted six or seven days, when it became distinctly located at McBurney's point. Within twenty-four hours from this time, the pain became localized and had increased in severity until it was hardly bearable. It required from four to six grains of sulphate morphine in the twenty-four hours to give him relief. This intense pain lasted at this point for about four days, when, all at once, the pain left McBurney's point, and extended along Poupart's ligament down the right thigh. There was also intense pain in the lumbar region. There was no vomiting during the entire course of his illness, but intense nausea was constant. The doctor has no remembrance of having had a chill, nor even chilly sensations. About twelve days before the operation, the doctor's wife took his temperature and it was 102° F. From this time up to the hour of operation his temperature ranged from 100 to 103° F.

November 11th, Dr. A. F. Richards of Sparta was called to see the case, in the absence of Dr. R. E. Lee Smith of Doyle Station, who was detained at the bedside of his dying mother. I will state here that Dr. Smith saw the doctor during the first part of his illness and from the headache, anorexia, the malaise, and so forth, diagnosed it slow fever—a diagnosis I believe any physician at that time would have made. When Dr. Richards saw the case two days before the operation, he diagnosed an appendicular abscess, asked for consultation and they telephoned for me.

After examining the patient, I agreed with Dr. Richards that there was an abscess, but leaned to the opinion that it might be a psoas abscess. So soon as we could procure help from Sparta, fifteen miles distant, assisted by Drs. Richards, Moore and Gist, I opened the abdomen close to the anterior superior spine of the ilium, hoping that we might be able to open the abscess cavity without going into the general peritoneal cavity. But we found this impossible, as we discovered a post-cecal collection of pus. There were no adhesions along the parietal peritoneum and we could sweep our fingers around over the abscess sack, under the anterior abdominal wall—it reminding one of a football in size and shape. It was very fortunate that I made the incision where I did, for the intestines and omentum were all matted together with masses of lymph walling off the pus from the general peritoneal cavity; and there was no space in which an opening into the pus sack could be made without difficult and dangerous dissection, except a space the length and width of the little finger right next to the bony wall. When I entered the abscess cavity with a bistoury, after packing off the general cavity, the pus squirted past the knife to the height of two or three inches. On further enlarging the opening, very offensive pus poured out over the side of the patient, reminding one of water pouring from the spout of an old-fashioned teakettle. The quantity of pus was estimated to be more than a quart. After cleansing the sac as best we could with iodoform gauze, it was gently packed with the same material and the external dressing applied without even irrigating, much less hunting for and attempting to remove the appendix. The patient made an uneventful recovery without a fistulous opening. I wish to state, much to his diagnostic acumen, that Dr. McC. (the patient) believed for some days before the operation that he had an appendicular abscess.

In January, 1901, a few weeks after the wound had entirely healed and the Doctor considered himself well, having regained his former weight and so on, he was taken with a severe attack of influenza. His temperature ran high and the cough was violent and spasmodic. After a day or so there was pain at the site of the old abscess during each paroxysm of coughing. Soon a distinct induration was felt in the region of the scar.

Dr. McC. being so far from a physician (ten miles) decided to be moved to Sparta, fifteen miles distant, where he could have constant medical attention. When he reached Sparta Dr. Richards and I were telephoned for and after a consultation with Drs. Smith, Gist, Breeding and Snodgrass, we deferred operating again until the symptoms were more pronounced. While we procrastinated the abscess ruptured in the scar of the abdominal incision on the day and just a few minutes before the hour set to do a second operation and in the presence of Drs. Smith, Gist, Snodgrass, Lee, Richards and myself. With a soft rubber catheter we washed out the pus sac and again packed it with iodoform gauze without an anesthetic. Dr. McC. remained in Sparta some two or three weeks and the wound was packed every other day by Dr. Richards. After returning to his home, where there was no other physician, his wife packed the cavity. To-day he is

stout (weighing over 200 lbs.), and well, except for this fistulous opening.

Just what the attack of influenza had to do with the return of the abscess, I am not prepared to say. Some French surgeons claim that the germ of influenza quite frequently plays an important part in the production of appendicitis. I am of the opinion that the Doctor is now ready for the removal of the appendix by a secondary operation.

After searching through the literature on appendicitis at my command I find other physicians have met with cases similar to the two I have just described. Among the most interesting are those reported by Dr. H. A. Hare of Philadelphia in the MEDICAL NEWS of July 21, 1900, in an article, "Appendicitis and Typhoid Fever." One case was so strikingly similar to one of my cases, I shall take the liberty of calling your attention to the principal features.

"A young man twenty-one years of age had not been feeling well for several weeks during which time he had a headache. He first complained of pain in the left hypochondrium and in the epigastrium although the entire abdominal region seemed unduly sensitive. There was pain on pressure over the appendix and virtually every symptom necessary for appendicitis—slight rise of temperature, quick pulse, and the abdomen scaphoid. On the second day the pain was markedly increased and was limited to McBurney's point; the abdomen was distinctly hard and board-like. The second day after entering the hospital the symptoms were so typical that Dr. Keen was called in to operate for appendicitis. He agreed with Dr. Hare and they decided to operate in the afternoon, but in the absence of Dr. Keen the patient grew so much worse, Dr. Hearn was called in to do the operation. He concurred in the diagnosis of appendicitis, and urged an immediate operation. Just before beginning the operation the tongue was again examined and on account of it looking somewhat typhoidal, the operation was again postponed. The next day the symptoms were no worse, and to state matters briefly the symptoms gradually faded as those of typhoid fever became more and more accentuated, and at the end of the week all the symptoms of appendicitis had disappeared and typhoid fever was present in its fully developed form."

Dr. Hare states in this paper that he had several just such cases, and it is my opinion that most every practitioner has had similar cases, which he can call to mind or else has overlooked.

The cases reported would naturally suggest the question, When should we operate for appendicitis? There is another question I would like to have discussed by the members of this society, When a large appendicular abscess is opened and the pus evacuated, should we search for and remove the appendix in all cases?

In answer to the first question I might say a great deal would depend upon what the patients and their friends would have to say. During fourteen years of country practice I find that the laity are usually "bitterly opposed" to surgical procedures, however simple they may be, and this I believe to be occasioned by too great conservatism on the part of the country physician. I have now under palliative treatment two uterine cancers which in a short time must carry their victims to a premature grave. Had they applied to a competent surgeon and submitted to a hysterectomy, their lives, in my opinion, could have been assured, so far as this insidious enemy was concerned.

I cannot refrain from saying "Like priest, like people," and we might just as truthfully say "like physician, like patient." We should ever be fresh on the differential, diagnostic points of medical and surgical cases. I am quite sure one reason we country physicians do not meet with as many cases of appendicitis as our city compeers is from the fact that we often fail to make the proper diagnosis. For the same reason we do not so often encounter ectopic gestation, a condition some authorities claim should occur quite frequently in the practice of a physician, doing even an average practice, and it is for the same reason we infrequently have cholelithiasis to treat. From some tubulated postmortems they report one-third of the subjects possessed gall-stones.

I am not an extremist for cutting. There is a beautiful mean, the haven for our patients. Let us not be too handy with our scalpels. Upon the other hand, we should fight against "old fogyism" and the hypnotic state, too conservative and not quite enough preservative. Let us educate our patients that honorable surgery is not butchery, that palliative medicine in operable cases is a deadly dose, and that procrastination in such cases is the thief of their lives.

I would answer the second question by stating that there are cases where I would not be justifiable in attempting to remove the appendix, but for Deaver and surgeons of his skill it possibly might be entirely the proper procedure.

THE PHYSICIAN IN RELATION TO THE DISPENSING OF MEDICINE.[1]

BY J. TRACY MELVIN, M.D.,
OF SAGUACHE, COLO;
UNITED STATES EXAMINING SURGEON; COUNTY HEALTH OFFICER; MEMBER OF THE AMERICAN MEDICAL ASSOCIATION; MEMBER OF THE THIRTEENTH INTERNATIONAL MEDICAL CONGRESS (PARIS); MEMBER OF THE CONVENTION FOR REVISION OF THE U. S. PHARMACOPŒIA, ETC., ETC.

FROM many and varied sources there comes unmistakable evidence that a radical change is taking place in the feeling of the profession throughout the country, regarding the dispensing of medicine direct to the patient by the physician. This is evidenced by the discussions in both medical and pharmaceutical journals, by the acknowledged marked diminution of prescription work in the leading pharmacies, both in the East and West, and in the greatly increased business reported by all the great manufacturing phar-

[1] Read before the Colorado State Medical Society, June, 1901.

macists who cater directly to the physicians' trade. Is this a step backward or forward?

We have noted in our own country the transition of the modern physician, with his smart little case containing practically no medicine from him of the capacious saddle-bags and ample attic supply of fifty years ago or more. We have seen at least one generation of doctors rise up which is as profoundly ignorant of the physical, chemical or botanical properties of the drugs which he uses in his battle with disease as it is possible for any educated man to be. We have seen students graduate from the foremost medical colleges who, after four full years of most diligent study and research, knew of no way of differentiating potassium iodide from common salt or Epsom salts from oxalic acid at the bedside. We have seen many older practitioners who did not know what the U. S. Pharmacopœia was, or its authority. And must we not, nearly all of us, admit that we receive even to-day a large part of our supposed therapeutic knowledge from the innumerable alleged medical journals which flood our mails and which are published solely in the interest of secret and proprietary remedies, often combined in "prescriptions" fearfully and wonderfully devised? Should we not hesitate, then, before changing to a system which will at least presuppose a confidence in the remedial effects of the drugs we use, a knowledge of their physiological action and the ability and willingness to observe results closely and to judge fairly?

We recognize that in times past a dispensing physician has been a term of opprobrium no less severe than that of a prescribing druggist, but this should not prevent our willingness to study present conditions and future prospects along this line. There are doubtless many men whose time is so fully occupied and who have at their command an educated and conscientious pharmacist, that they would seldom care to consider the question of their dispensing any medicines whatever except in some emergency, but the average practitioner, even in the city, I find is constantly using a more generous pocket case and seldom cares to-day to write a prescription for a few tenth-grain calomel powders, or for a couple of Dover powders. It is vastly easier to hand them out from his pocket case in the form of tablets.

But to those of us who practise in smaller towns or in the country, where perhaps we must rely upon the ordinary druggist of uncertain attainments, of limited experience and of doubtful stock, this becomes a more vital and important question than many others upon which we devote much time at our annual meetings and in our journals.

Can we be more certain in the results, more accurate in our dosage, more satisfactory to patient and friends, by dispensing our remedies ourselves at the bedside, than by sending our prescriptions to the pharmacist if there be one? If all these points can be answered in the affirmative our duty is plain and discussion useless, except as to ways and means. It is true that in many of the country districts we have been compelled by our environment to adopt this plan, whether it is really best or not, because of the long distance from any other source of supplies, but the question is, Should the practice be more general and from choice, not necessity.

As to certainty in results, I do not belong to the school of therapeutic nihilists myself. I do not believe that six weeks in bed is the only efficient treatment for rheumatism, or that four weeks in bed with cold baths and proper diet is even a rational complete treatment for typhoid fever, notwithstanding its advocacy by honored clinical teachers. Still, as I have stated in a previous paper presented to this Society, I do believe that most of the Galenical preparations of even our best pharmacies are uncertain and unreliable from their very nature and because of the necessary constant variation in their real medicinal content. The remedies dispensed by the modern physician are not so, being as a rule definite permanent alkaloids or active principles, accurately divided in definite doses by the granule or tablet form in which they are used and expressly prepared for this purpose, making the medication as certain as possible in its results; while its form, which may be modified as a pill, powder or solution, one remedy or several combined, gives unrivaled opportunity to adapt the remedy to the particular case in hand.

Is it more satisfactory to the patient and friends? That must be a matter of personal observation in each community. My own experience is very strong that it is. We all recognize the value of the personality of a physician in inspiring confidence in his patient, and where the patient observes this physician in whom he has such confidence selecting and preparing his medicine right there at the time of his visit, his confidence in a favorable result is immensely increased and no chance is left for those lurking suspicions so natural at such a time, that maybe the druggist did not prepare it properly. It is true that under such circumstances if the results are not what the physician would wish, he cannot lay the blame on the druggist. I cannot too strongly urge this point of the increased satisfaction which medicines given by the doctor give both patient and friends. Another great advantage is the opportunity for making such changes as the progress of your case may demand without attracting notice. We may leave medicine in the morning and find by evening that conditions are quite different from what we supposed or expected. A new prescription, the discarding of the previous medicine, all attract attention and comment, while the dispensing physician may modify, renew or discard with none but himself to consult.

Another important point is the ease with which we may obtain our results by this method. I suppose that there are few of us to-day who do not recognize the general rule of giving any medicine which may be indicated by itself, if

possible, until its definite therapeutic or even physiological effect has been obtained. This means an extremely variable dose which can seldom be provided for as the case progresses unless you are dispensing the medicine yourself, but never under any circumstances where you are drawing your supplies from Galenical preparations of varying strengths, differing ages, unknown origin and from competing pharmacies.

If, then, we conclude that this system is better, safer and more satisfactory to the patient, is it practical, is it wise, is it desirable for the physician? I have already intimated several ways in which it is of advantage to him and I might mention another point of no little importance to those of us who depend solely upon family practice, and that is that in this way we retain a large amount of minor work which otherwise would not come to our office at all. There are very many cases of slight fevers, indigestions, headaches, coughs and bowel troubles which are commonly treated in the family, by the advice of friends or of the druggist, which under this system come to be placed more and more under the care of the family doctor. Not always do these cases mean a straight office fee, but at least they mean something, besides giving one a closer hold upon the family. On the other hand, the question arises, Is such a plan practical for the average practitioner? Does it not involve too much expense without return? Are not there chances for serious mistakes? In a word, does it not add to the burdens of the physician rather than lighten them? I have not found that any of these objections hold good. Almost the only reason why our predecessors so largely abandoned dispensing and began prescribing was because of the skilled labor and complicated processes necessary to extract the medicinal activity from plants, the bulky and inconvenient form in which nearly all medicine existed and the liability to mistakes and errors in guessing at the different doses by the bedside. Now all of this has been wholly changed. Granules and tablet triturates enable one to carry in a two-dram vial the active principle in convenient, accurately divided doses, equivalent to one quart of syrup of ipecac, and proportionally of other remedies. In fact, a thin pocket-case will to-day hold more real medicine than the largest buggy-case of twenty years ago.

For we must recognize that pharmacy has changed during the past thirty years no less radically than medicine and surgery. No longer does the druggist gather his herbs himself or buy them of those who do. Seldom does he even make his own preparations from them, and never does he pretend to extract the active principles or to manufacture his chemical salts. No, progress in this line as in all others has been toward eliminating all of these operations on a small scale and confining them to those great manufacturing houses where unlimited capital provides the highest skill, the most perfect apparatus, the most extensive gathering of their supplies and their most rigid testing, chemical and physiological. If the average druggist has become, by the force of these conditions, merely the merchant whose business is the buying and selling of certain articles, and such is the case in more than nine-tenths of our pharmacies, why should we still possess the delusion that he is a necessary professional partner?

It is objected that when once a physician limits himself to those remedies which he himself carries, he gets into ruts and makes a limited assortment answer when perhaps he would make a wider selection more accurately fitted for the case in hand were he prescribing from a well-supplied drug-store. Theoretically this appears to be true, yet it is almost humiliating to find within what narrow therapeutic lines our most prominent men confine themselves. There are to-day in our Pharmacopœia more than nine hundred official remedies and we know that very many of those most used are not yet official, yet in one of the largest hospitals in this country, with their staff of over one hundred physicians, I found their dispensary to contain less than one hundred remedies and almost three-quarters of their three hundred daily prescriptions were prepared from twenty-five of these. My experience of many years behind the prescription-counter in this and other cities proved to me again and again that ninety out of every hundred consecutive prescriptions by any one man could be prepared with a list of thirty-five remedies. Of course, a larger number taken consecutively would show a wider variation owing to the changing seasons and the trial of newly recommended drugs. So I would submit that an average practitioner can readily select, say, fifty remedies or combinations, which will include all that he will under any circumstances use in nine-tenths of his work, and with them he will form combinations more efficient and more acceptable in every way to the patient than the prescriptions he writes, for in this way he will learn how atrocious some of the recommended formulæ in our standard text-books are to sight and taste, especially if he tries to administer them to children. These fifty selected remedies would not occupy six feet of narrow shelf-room and half of them would be needed in the pocket case. One's location and surroundings and one's own experience would say to what extent this stock should be increased. In my own case, although I have for years owned the only drug-store in our community, I have found it far more satisfactory in every way to attach a complete dispensary to my office, and provide it with every convenience for easy and accurate work, so I find that I have over six hundred remedies and preparations on my shelves, yet of my last thousand prescriptions, for I keep as accurate a record of all medicines dispensed, as though the prescription was to pass through another's hands, nine hundred and twenty were drawn from a group of forty remedies of which twenty-two were alkaloids, five synthetics and thirteen chemical salts.

In conclusion, I would only enter a plea for a thoughtful recognition of the changed conditions of to-day and for a return to that accurate, well-trained clinical observation of the actual effects of every remedy administered by the physician in each case that he treats, to the end that the vast mass of therapeutic trash which now confuses and misleads us may be wholly swept away and that the physicians of the present and future may be so trained and educated as to give to this most important branch of our profession, that same skilled attention, born of scientific laboratory methods, which they now give to differential bacteriological diagnosis or to blood-examinations.

This will only be when our colleges and the profession at large will have turned from the traditions and customs of the past and brought themselves into the closest possible contact with the Nature and peculiarities of the weapons which they are using and their improved and modern forms.

ANCHYLOSTOMA DUODENALE IN TEXAS.[1]

BY M. CHARLOTTE SCHAEFER, M.D.,
OF GALVESTON;
PATHOLOGICAL INTERNE OF SEALY HOSPITAL, GALVESTON.

While anchylostoma duodenale has been widely recognized as a parasite of the human intestine in various tropical and subtropical regions of both hemispheres, its observation in the United States has been extremely rare. It was recognized[2] as early as 1830 in Louisiana by Chabert and in 1840 by Duncan, and in Georgia by Lyell in 1849. Blanchard[3] mentions its observation also in South Carolina by Heusinger and Geddings and in Florida by Little and Letherman. In 1867 White[4] exhibited before the Boston Society for Medical Improvement several specimens of the worm which, however, were obtained from a patient of Dr. Wucherer in Bahia in Brazil. In 1893 Blickhahn of St. Louis[5] encountered a case in the person of a German recently immigrated into this country, and specimens of the parasite from this source were demonstrated before the Philadelphia Pathological Society by Stengel about the same time.

In 1894 in a paper read before the Texas State Medical Association upon observations upon human parasites encountered in his forty years of practice of medicine, F. Herff of San Antonio[6] mentions the case of a Mexican woman in whom at autopsy he encountered several examples of what he believes to have been the parasite in question; and refers to having met with the symptomatology of the worm in several Italians under his care at a later period.

In a hasty examination of the usual works of reference the writer is unable to meet with other instances credited to the observation of American, particularly Texas, physicians, and therefore believes the records of the following case worthy of presentation, particularly as there is distinct reason for believing the parasite a not very uncommon, but generally disregarded one in this part of the world. In the summer of 1893, while demonstrating to a private class the microscopical characteristics of the human stool, the material being obtained from the general closet of the medical school in Galveston, Dr. Allen J. Smith encountered the ova of the parasite in considerable numbers, but was unable to find the person from whom the stool had been discharged. In the winter of 1898-99 he twice encountered very similar worms in the intestines of dogs killed in experimental work in the institution, two specimens from this source, attached to the intestinal mucous membrane, being now exhibited in the museum of the school. Since the recognition of the case to be described a similar discovery of ova in the fecal matter taken from the closet for the purpose of class demonstration has been made with this in view, and led by the general symptoms of the patients and the discovery of more or less well-marked eosinophilia in the blood of two of the medical students apparently suffering from malarial attacks, Dr. Smith has examined the stools of both subjects and succeeded in demonstrating the anchylostoma ova in both. In the first of these two cases the malarial parasite was also met, and after a few days the patient went home before measures for the elimination of the intestinal parasite could be taken. In the second case no malarial hematozoa were found after repeated and prolonged search; on April 22d, after the administration of large doses of thymol, two female anchylostomata were obtained by Dr. Smith.

It would seem, therefore, that hitherto insufficient attention has been given to the possibility of the existence of this worm in patients living in this region, and that it is desirable in cases of indefinite anemia associated with gastro-intestinal disturbance, and perhaps edema and irregular febrile paroxysms similar to those of malarial fever, to make careful microscopical examinations of the fecal matter with a view to recognizing or eliminating the possible influences of this worm.

The case under personal observation is a patient in the United States Marine Hospital wards in St. Mary's Infirmary at Galveston, under the care of Dr. W. Keiller to whom the writer wishes to express appreciation for the courtesy in permitting this presentation.

G. S., white, sailor, aged forty years, born of American parents in Melbourne, Australia, where his father was a merchant. There is nothing of special importance in his family history, his father dying from cardiac disease at the age of fifty-two years, his mother from unknown cause at the age of sixty-two or sixty-three years, and the one other child, a brother,

drowned. The patient lived in Australia until eleven years of age, when he went to sea, and since then has spent most of his life as a sailor upon American vessels, for the most part in long voyages between New York and China *via* the Cape of Good Hope. During his seafaring life his health has been invariably excellent, the present illness being the first compelling him to go to bed for any protracted period. In the early part of last August he accepted a position as overseer upon a large plantation in the State of Chiapas in the southern part of Mexico, remaining in service at this place sixty-five days before his failing health forced him to leave. The patient attributes his present illness wholly to the effects of drinking notoriously unfit water from a creek and river from which all the water supply of the plantation was obtained. While after heavy rainfalls the river water was not unpalatable, at other times it became greenish in color and nauseating to the taste. Large numbers of persons employed upon the plantation had been known to sicken and often to die, not only the overseers and workmen, but women and children, who are not engaged in any of the field work, almost all after the same train of symptoms presented by the patient; and even the Indians rarely remained in the locality more than a week or ten days, invariably leaving because of the lack of proper water. Two days after the arrival of the patient at this plantation there came a colony of about seven hundred Russian peasants to work upon the estate, and in the sixty-five days of his stay there the patient states that no less than three hundred and seventy-eight had died; many others had left and most of the few who remained were sick, pallid, emaciated and often dropsical. Nearly all took sick with vomiting, bloody diarrhea, developed an intermittent type of fever and rapidly wasted. After the disease had proceeded some degrees the limbs usually became swollen, the dropsy extending in some instances to the abdomen, and generally after the development of the edema death occurred.

The food served on the plantation the patient describes as not very agreeable; for the most part it was well enough cooked, but the service at table was not appetizing. It consisted mainly of frijoles and rice with fresh meat about three days in the fortnight. Aside from these features the patient is unable to indicate any definite fault in his mode of life at the plantation in question. After he had been on duty at this plantation for about two weeks (about the middle of August) he lost his appetite and became nauseated; presently persistent vomiting and diarrhea set in, and he developed irregular malarial-like febrile paroxysms. These symptoms persisted and became severe; after the seventh week he rapidly lost weight and strength, so that about the tenth week he was forced to relinquish his position and make his way back to the coast. When he left Vera Cruz for the plantation he weighed 175 pounds; when he left his weight had fallen to 125 pounds. He returned to the coast and remained there for several weeks until an opportunity to ship on a schooner bound for Sabine Pass was afforded. He remained at Sabine Pass for several days, then came to Galveston, arriving on December 21st, and at once entered the hospital. On the trip from the Mexican coast he improved somewhat generally and was able to take a hand at the wheel, but was unable to do the general work of a seaman. When the diarrhea first set in it was not dysenteric in character, but about September 10th he began to note the presence of blood in the discharges, and during the remainder of this month and the early part of October considerable blood and mucus were constantly present. Much tenesmus accompanied this diarrhea, especially during the time when most blood was being passed, the pain being so great that at times when at stool he lost consciousness. At the worst period the discharges were very frequent, as many as several dozen in the twenty-four hours, the least solid or liquid food, especially water, being at once followed by intense tenesmus and an urgent desire to evacuate the bowel. After leaving the plantation this condition improved somewhat, the discharges becoming somewhat formed and reduced in number to about seven or eight in the day. After he shipped on the schooner to Sabine Pass they were further reduced to about three or four in the twenty-four hours, and remained thus without much blood showing up to the time of admission to the wards. During this period of diarrhea and emaciation the patient's appetite was absent, he became very pallid and icteroid, and at irregular periods there were paroxysms of chills and fever. In the latter part of October, while on the Mexican coast before shipping to Sabine Pass the patient first noticed that his feet and ankles were becoming swollen to the extent that he was unable to wear his boots; the swelling was accompanied by considerable discomfort from the tenseness of the skin and from more or less severe rheumatoid pain in the limbs and feet. The skin of the ankles and feet became diffusely bronzed and several large bullæ appeared upon both feet and ankles, filled with an acrid, clear serum, and healing without scar formation after being punctured several times in different places.

When the patient was admitted to the Marine Hospital wards on December 21, 1900, his condition was as follows: He is a man five feet and ten inches in height and weighs about 125 pounds, much emaciated and pale, with a distinct icteroid tint of the skin and conjunctivæ. He is very weak, but able to stand and walk about the wards; the ankles are diffusely pigmented and pit deeply on pressure, the edema extending as high as the knees. He complains of considerable discomfort from the latter and a dull pain in the limbs, as well as of some discomfort and tenderness in the abdomen, particularly in the region of the spleen. Examination of the chest shows no important pulmonary alteration; the respirations are variable, sometimes slow, sometimes

rising as high as thirty to the minute, and generally rather shallow. The pulse is generally rapid (about 100 per minute) and soft; and a soft systolic murmur can be heard in the mitral areas. No enlargement can be detected in the hepatic or splenic areas; but there is decided tenderness in the left hypochondrium.

About the time of admission the temperature was elevated to 38.9° C. (102° F.), falling the next day to about normal; on the third day slightly subnormal; on the fourth, 38.2° C. (100.7° F.); on the fifth, 36.6° C. (97.9° F.); on the sixth, 38° C. (100.4° F.); on the seventh, 37.9° C. (100.3° F.); on the eighth, the same; on the ninth, 37.3° C. (99.1° F.); on the tenth, 39.6° C. (103.3° F.); on the eleventh, 36.7° C. (98.1° F.); on the twelfth, 40.5° C. (104.9° F.), and thus onward, for the most part nearly normal or slightly subnormal, with irregularly appearing accessions corresponding to malarial-like paroxysms in which the temperature would often mount to over 40° C. (104° F.).

These paroxysms, while rather irregular, were in their occurrence somewhat suggestive of a quartan type of malarial fever, and at first a tentative diagnosis of this affection was made and the patient treated accordingly. Repeated examination of the blood by the writer and others failed, however, in every instance to detect the hematozoa, although there was always recognized a distinct leucocytosis in which an eosinophilia was apparent. Administration of quinine and of arsenic apparently had no effect upon the paroxysms or upon the general trend of the disease. On January 25th the writer detected *ameoba coli* in the stools, although the probability of their presence as accounting for the dysenteric symptoms had been previously recognized and treatment for the relief instituted with considerable benefit. At this time the ova of the anchylostoma were overlooked, and it was not until February 17th that the writer while making a careful examination of the stool encountered these objects. At this latter date the stool was soft and unformed, of a rather reddish color from the diffuse admixture of blood; numerous amebæ were met with in active movement, as well as trichomonads. The ova found were in considerable numbers, every specimen of the matter put under the microscope containing several. They were clear, oval bodies, measuring from 55-60 micromillimeters in long diameter, and about 45 micromillimeters in transverse diameter. Within was to be seen a yolk substance in varying degrees of segmentation, usually four or five divisions showing clearly. These objects were, after discovery, readily identified as the eggs of the anchylostoma, and accordingly reported together with the other parasites and the blood and mucus everywhere met with in the specimen. On February 20th, while this stool was being demonstrated to the class in the medical school, a few eggs of the *trichocephalus dispar* were encountered by members of the class and reported to the writer by Dr. Smith. In the meantime, on February 18, Dr. Keiller with a view of expelling the anchylostomata had administered the ethereal extract of male fern, sending all stools to the pathological laboratory for recovery of any parasites passed. On February 19th the first stool following the administration of the anthelmintic was washed through a fine screen of cheesecloth, but no parasites were found. On the following day a second specimen was washed and in this one male *trichocephalus dispar* was found. At about this time the general condition of the patient was more or less alarming and the prostration was such, taken with the frequent and severe febrile paroxysms, that active measures for the expulsion of the worms from the intestine were suspended until March 7th, when the patient had partially recovered his strength. Thymol to the amount of a dram and a half, given with the usual preparation and precautions as to the avoidance of oils and alcoholic substances during the period of its presence in the body, was administered upon the latter date. In the stools following this administration there were found between ninety and one hundred anchylostomata, but no trichocephalids. Almost immediately after recovery from the exhaustion of the remedy the general condition of the patient began to improve, although the general symptomatology was maintained in less severe form. Subsequent examination of the feces showing the persistence of ova of both parasites on April 18th, the thymol was repeated and the stools for the next forty-eight hours washed through a sieve of cheesecloth; on this occasion six or eight more anchylostomata were found, but no trichocephalus. To the present time eggs remain in the stools, but in diminished quantities, and further administration of the anthelmintic is required. The patient is much improved, the icterus is entirely gone, the edema has disappeared, and the febrile symptoms have much abated, but as late as April 21st a paroxysm in which the temperature mounted to 39° C. (102.2° F.) occurred, although for ten days before this there had been an almost normal temperature. The patient is still very anemic, but seems to be slowly improving in this respect and has gained somewhat in flesh and strength.

A blood-count made upon February 17th when the parasites were first found showed a reduction of the red cells to 2,970,000 and an increase of the white cells to 14,300 per cubic millimeter; and upon the following day at 3 p.m. the hemoglobin content was estimated at 57 per cent. The enumeration of the leucocytes at this examination showed the polynuclear and polymorphoneuclear elements to represent 90 per cent. of the total number, the large mononucleated, 2.4 per cent, the small mononucleated, 1.6 per cent., and the eosinophiles, 6 per cent.

Owing to the recent illness of the writer these observations have not been repeated; but several examinations of the blood have been made by Dr. J. T. Moore (to whom she is indebted for the

leucocyte-count just given) for malarial organisms, invariably without result.

The urine has been repeatedly examined by the writer and others and has always failed to show albumin, casts or other elements of special import.

MEDICAL PROGRESS.

Psychical Troubles in Paludism.—While writers on marsh fevers from the time of Hippocrates have time and again referred to the delirium which occurs in the course of such fevers, the abnormal psychical states associated with paludism have not been carefully studied until a comparatively recent date. The subject is carefully considered by J. P. CARDAMATIS (*Le Progrès Méd.*, Sept. 28, 1901) who distinguishes several classes of cases. The psychical troubles of paludism may be (*a*) psychonervous states occurring during the paroxysm of simple intermittent fever; (*b*) disorders occurring in the course of chronic paludism, either accompanying the febrile movements or manifesting themselves in the intervals; (*c*) psychical disturbances associated with remittent or pernicious fevers; (*d*) psychoses of malarial cachexia. It is not the malarial parasite, but the toxins produced by that factor, which constitute the direct pathogenic cause of the various nervous and mental symptoms. The psychoses in question may occur in any victim of the plasmodium, but they are most likely to attack individuals neuropathically disposed; paludium evidently is capable of awakening a morbid predisposition previously latent. Paludal delirium should be classed with other forms of toxic delirium, occurring in infectious diseases. According to the predisposition of the individual and the quantity of active toxin present, one of four degrees of intoxication is produced, namely, excitation, anesthesia, coma, paralysis. The psychoses of chronic paludism are rare, while the real cause of those which are said to occur long after the cure of the malarial condition proper is open to question.

Treatment of Asthma.—The cause of asthmatic attacks, according to G. R. JOHNSON (*Med. Times*, Oct., 1901) depends upon the arterial tension to a large extent and hence indirectly diet becomes an important factor in the treatment. Meats, soups and meat extracts should be avoided as poison, for they are rich in uric acid, which stimulates contraction of arteries. Milk, fruit and vegetables should compose a large part of the diet. A few successful therapeutic combinations are given:

℞ Potas. Iodid.....3iij
Ext. Bellad. Flu.....3j
Ext. Lobel. Flu.....3ij
Ext. Grindel. Flu.....ʒss
Glycerine } aa.....ʒiss
Aquæ }

M. et Sig.: Tablespoonful every two to four hours.

A good external application is:

Chloroform.....ʒss
Olei Terebinthinæ.....ʒi
Sprts. Rosmarini.....3iss

In the suffocative stages of asthma the following is recommended:

℞ Tinct. Lobeliæ.....ʒss
Tinct. Sanguinariæ.....ʒij
Olei Menth. Viridis.....ʒss
Syrupi Empyreumatici.....ʒv

Sig. Half teaspoonful every two hours.

Congenital Heart Disease.—Of 32 such lesions occurring in the practice of J. L. MORSE (*Archives of Pediatrics*, Oct., 1901), the diagnosis of patent foramen ovale was made in 6 cases, patent ductus arteriosus was presumed in 5 and defect in the ventricular septum in 6. In 17 the chief lesion was thought to be at the pulmonary valve. Two of the cases with patent foramen ovale were premature. One case had clubfeet, one was microcephalic, and one developed hydrocephalus. The sexes were about equal. The symptoms complained of were cyanosis in 17 cases, dyspnea in 6, cough in 5, convulsions in 2, edema in 1, and in 14 the lesion was discovered accidentally. Cyanosis was the most common symptom, others being recurrent attacks of severe dyspnea, convulsions, edema, and cough. None of the cases diagnosed as patent foramen ovale died. Six died of the heart disease at 3, 6, 8, 9, 10 and 12 months; 6 died of other diseases; 5 have passed successfully through measles, 8 through scarlatina, and two through whooping-cough.

Myeloma of the Spine with Compression of the Cord.—These tumors produce various symptoms, the most constant being pains in the chest, back and extremities; deformities; gradually increasing anemia. In a case observed by J. J. THOMAS (*Boston Med. and Surg. Jour.*, Oct. 3, 1901) there were symptoms due to pressure on the cord. At a late stage the gait was *spastic-ataxic;* Romberg's symptom was present; there was incoordination of the legs, slight disturbance of the sense of position, marked general paresis of the legs. The muscles reacted normally to the faradic current. The knee-jerks were equal and increased, and there was slight patellar clonus, and ankle clonus on both sides. The plantar, cremasteric, abdominal and epigastric reflexes were absent. The sense of pain and temperature was absent, that of touch diminished. A perusal of the literature shows that albumose was present in 11 of the 19 authentic cases that have been reported. Its presence should at least direct attention to the possibility of disease of the bones.

Gluten and Anti-Diabetic Foods.—An analysis was recently made of various food products sold under the name of gluten and diabetic foods with a view of determining whether any material change had been made from the ordinary

wheat and graham flours. H. C. Sherman and H. M. Burr (*N. Y. Med. Jour.*, Oct. 12, 1901) obtained twelve samples of such foods from various manufacturers and analyzed them most carefully. It was found that not half are noticeably higher in protein or lower in carbohydrate than the ordinary whole wheat flour, and many are scarcely better than white flour or bread. The best sample examined contained twice as much carbohydrate as protein.

Eye-Lesions of Syphilis.—Primary syphilis occasionally appears on the eyelid or conjunctiva, writes Frank Buller (*Montreal Med. Jour.*, Sept., 1901), and secondary syphilis gives a fair number of cases of iritis, but hereditary syphilis, and much more the tertiary stage of acquired syphilis cause most of the syphilitic eye lesions. The interstitial keratitis of hereditary syphilis is seldom treated as such by general practitioners and much harm is done. A true interstitial keratitis may also be a tertiary manifestation. Another specific keratitis is characterized by superficial and deep circumscribed, densely white opacities, very irritative but not tending to ulcerate or become vascular. Every form of specific keratitis is attended with a tendency to iritis. The important lesions are (1) simple plastic iritis, the most common; (2) nodular or gummatous iritis, absolutely pathognomonic, and occurring between six and nine months after the original infection; (3) iritis secondary to choroido-retinitis, indicated by opacity of the vitreous; (4) scleritis resembling the ordinary rheumatic form; (5) gummatous cyclitis, very rare; (6) violet retinitis and much opacity of the vitreous; (7) a milder, more chronic and often relapsing retinitis; (8) optic neuritis, mostly a descending neuritis, due to some coarse intracranial lesion, but sometimes purely local; (9) monocular irido-cycloplegia due to disease of the ciliary ganglion. To these may be added many paralyses of the extrinsic ocular muscles. With but few exceptions these recurring lesions followed long routine treatment by proto-iodide of mercury, varied at times by potassium iodide medication. The best general method of mercurialization is by inunction, though gray powder, vapor baths and hypodermic injections are also effective. The patients should always have tonics as well.

Multiple and Solitary Adenoma of Liver.—Adenoma of the liver is regarded as a congenital new growth by A. Engelhardt (*Deutsch. Archiv f. klin. Med.*, Bd. 63, Heft 1 *u.* 2). The condition presents no reliable diagnostic features. It is frequently associated with cirrhosis, the two pathological changes being independent results of a common cause. A case of multiple adenema with cirrhosis was observed by Engelhardt; clinically the picture was that of simple cirrhosis. The Caput Medusæ was well marked; the umbilical vein in the ligamentum teres remained patent. Thick, tortuous veins were developed on the surface of the liver; these were connected with the venous system of the parietal peritoneum and of the abdominal wall through the suspensory ligament. The liver was smaller than normally, and was studded with tumors of various sizes; these invaded the entire portal system, growing in the vascular walls; the hepatic vessels, arterial and venous, were absolutely free. Within the acini of the adenomata bile pigment was found. In certain areas necrobiotic changes had taken place within the cells. While hepatic adenomata were commonly described as having a poor vascular supply, the growths in this case were rich in capillaries both peripherally and centrally.

Bicycling: Its Indications and Contraindications.—By means of a gasometer attached to a bicycle the air expired by the rider has been collected for analysis, and the amount of energy liberated in the course of metabolism by this form of physiological exercise has thus been estimated. L. Zuntz (*Fortschritte d. Med.*, Sept. 22, 1901) shows that a rider who covers 15 kilometers in an hour liberates ten per cent. more energy than does a pedestrian who walks 6 kilometers in the same period; if the wheelman rides 21 kilometers the energy requirement is almost twice as great as that of the 6-kilometer pedestrian. Inasmuch as bicycling involves so extraordinary a consumption of energy and is accompanied by relatively slight sensations of fatigue, its place in the treatment of obesity would seem to be theoretically established. Like all active muscular exercise bicycling diminishes the quantity of sugar in the urine in diabetes. In slight degrees of anemia bicycling is of advantage as a stimulus to metabolism; in severe cases this form of exercise makes such demands upon the heart that it is contra-indicated. The use of the bicycle favors assimilation in chronic obstipation. Earlier literature contained frequent references to cases of inflammation of the knee-joint, said to be due to bicycling. Recently such cases have ceased to be reported, and it is probable that those originally cited related to individuals predisposed to arthritis. Faulty posture while riding no doubt leads to spinal deformity, and the danger of this result is especially to be guarded against in youthful riders. F. A. Schmidt goes so far as to advise that riding be forbidden to all children under twelve years of age. Many writers have recorded happy results from the adoption of wheeling by neurasthenics.

Lecithin in Tuberculosis.—The efficacy of lecithin in stimulating nutritive exchange has been scientifically demonstrated by Danilewski and Soromo, and later by Desgrez and Zaky. Gilbert and Fournier have shown that the administration of lecithin produces an increase of weight in cases of tuberculosis, neurasthenia and diabetes. The effects of lecithin in cases of tuberculosis are more satisfactorily shown by H. Claude and A. Zaky (*La Presse Méd.*, Sept. 28, 1901), who in their experimental and clinical studies gave special attention to urinalysis, not neglecting, however, to observe carefully changes

in body weight and in the general physical condition of the subjects of their experiments. They find that lecithin causes in tuberculous subjects a rapid modification in metabolism, which expresses itself by an immediate diminution in phosphorus elimination, and by a tendency to progressive elevation of the coefficient of nitrogen utilization. In subjects not in the last stages of chronic tuberculosis and not suffering from an extremely acute attack of the disease, the administration of lecithin produces promptly an increase of weight, stimulation of appetite, amelioration of the general condition. How far local lesions are affected is not shown, but in the opinion of the authors such lesions are modified as indicated by changes in physical signs. Lecithin is strongly recommended by these writers, if not as a specific, at least as an important adjuvant to other forms of treatment.

Gastrosuccorrhea or Reichmann's Disease.—Reichmann was the first to describe the continuous, spontaneous secretion, in the empty stomach, of a substance chemically and physiologically identical with the gastric juice which is ordinarily produced in response to physiological stimulation. A case of true Reichmann's disease is described by L. VON ALDOR (*Berl. klin. Woch.*, Sept. 30, 1901) who states that he has seen five such cases in all, carefully excluding, however, instances of symptomatic hypersecretion, such as is associated with hyperacidity and motor insufficiency. In these five cases the symptom-complex was at times so severe as to suggest the presence of malignant disease. Intense gastric pain occurred entirely independently of the taking of food; vomiting was frequent and copious, thirst excessive and constipation more or less stubborn in every case. The employment of the stomach tube and the careful investigation of the gastric function are indispensable in diagnosis. Characteristic features are (1) the presence of large quantities of gastric juice in the otherwise empty stomach; (2) the low specific gravity of the stomach contents; (3) the excessive acidity of the gastric juice obtained from the empty stomach as well as of that obtained after a test-meal—there is especially an excess of free hydrochloric acid, and to a less degree an excess of total acidity and of pepsin; (4) incomplete amylolysis due to excessive acidity. In Von Aldor's cases these objective findings persisted during periods when no subjective symptoms were present, indicating that the mere presence of the abnormal hyperacid secretion does not suffice to produce symptoms, the latter requiring in addition an abnormal irritability of the gastric mucous membrane. Treatment is most successful when belladonna preparations are used. While atropin is the most powerful agent known in the discouragement of gastric secretion, toleration is speedily acquired. Riegel's experiments have shown that morphine does not diminish gastric secretion at all but rather increases it; hence morphine must be avoided in these cases. While awaiting the physiological action of repeated small doses of atropin, the patient should be instructed to drink warm alkaline waters freely before and after meals. If with these measures we combine the daily administration of one or two drams of Carlsbad salts, lavage will rarely be necessary.

Hydrotherapy in Chronic Diseases.—Nowadays the methodical application of air, rest, exercise, diet and the internal and external use of water are important agencies in the removal of chronic diseases. Among these agencies water is regarded by S. BARUCH (*Boston Med. & Surg. Journ.*, Oct. 3, 1901) as the most indispensable because the most effective. Phthisis forms a striking illustration of the methods of hygienic treatment. The management now generally adopted in the best institutions combines the open air, dietetic and water treatment. Cold water has an irritant effect upon the sensory terminals in the skin; reflexly it causes deepening of respiration, improvement of the pulse, enhancement of glandular action and excretion, improvement of appetite, digestion and hematosis. By means of daily neurovascular training the patient's power of resistance is greatly enhanced. Neurasthenia has proved very amenable to hydriatic treatment. Exercise may be made an important curative factor in diabetes by stimulating the myolemma to utilize sugar. The great lassitude of the average diabetic precludes resort to exercise, but by judicious neurovascular training with cold douches lassitude is overcome. Cases of nervous dyspepsia are also fruitful for hydrotherapy after they have run the gamut from hot water and Salisbury steak to lavage. Charcot's success with cold douches in hysteria has been repeated by many others. Sciatica, neuritis and lumbago are greatly relieved and often removed by hot applications followed by cold douches. Angina pectoris being more frequently false than real, is often removable by hydrotherapy.

Effect of Climate on Nervous Diseases.—Therapeutic climatic results depend principally upon states of atmospheric pressure and the consequent nutritional improvement. F. S. PEARCE (*N. Y. Med. Jour.*, Oct. 5, 1901) says that functional diseases are more particularly influenced by climate. Great altitudes favor circulation in the periphery of the body and assist nutrition by increased absorption of nitrogen and by producing a more active circulation. A great altitude is not good for the neurasthenic who must appropriate nutriments slowly on account of the weakened central nervous system. Insomnia is benefited by lesser altitudes while chorea, hysteria and most of the functional maladies are benefited by life at the sea level. Melancholia and depressed states are helped by high winds and moderate heat. A greater altitude is desirable for diseases of central nervous system, a lesser altitude in cases of peripheral diseases.

Widal's Reaction in Children.—As the result of about 150 tests at the London Hospital for Sick Children, J. H. THURSFIELD (*Pediatrics*,

Oct. 15, 1901) finds (1) that in children's diseases a positive Widal reaction is evidence of the presence of typhoid fever; (2) that a negative reaction later than the tenth day is strong, but not absolute evidence of typhoid fever; (3) that repeated negative reactions are trustworthy evidence that the case is not typhoid.

An Obstetrical Outfit.—As an aseptic labor-bag, capable of holding everything necessary for a case, H. Judson Lipes (*Annals of Gyn. and Ped.*, Oct., 1901) uses a Rochester sterilizer, 16x6x6 inches, with two trays and canvas carrying case. In the lower tray are carried ether, alcohol, an alcoholic lamp, a canvas lithotomy sling, a 3-quart sterile douche-bag, chloroform inhaler and dropping-bottle, and forceps. The upper tray holds a Kelly-pad, operating-gown, rubber gloves, soap, brush, nail cleaner, bichloride tablets, ergot, acetic acid, boric acid, nitrate of silver solution, eye dropper, cord scissors, cord tape, needles, catgut sutures, silkworm-gut for perineal tears, scales, two artery clamps for grasping the cord instead of tying in case of emergency, a lisle-thread braided catheter, and a No. 22 English catheter with stylet for replacing cord, etc. If the case is far from home, he adds a rubber apron, scalpel and blunt bistoury, cranioclast, perforator, speculum, Barnes' bags, etc. If forceps or other instruments are needed, the sterilizer is quickly gotten ready and placed on a stove or over an alcohol lamp. Its lower part can be used for immersing the baby in asphyxia.

The Knot within the Lumen in Intestinal Surgery.—The possibility of introducing a proper intestinal suture without entering into the lumen of the gut is conceded by F. G. Connell (*Jour. Amer. Med. Assoc.*, Oct. 12, 1901), but this writer maintains that in locations other than the duodenum such an attempt is impracticable for the average surgeon. The importance of the submucous coat is recognized, but the difficulty of splitting its fibers is very great. If it is not included there is danger of yielding; if it is perforated the danger of capillarity presents itself. Connell prefers to run the lesser risk of capillarity and recommends a suture which includes all coats and is tied on the mucosa. The advantages claimed to be derived from penetrating all coats of the intestinal wall and placing the knot within the lumen are less danger of peritonitis through leakage at stitch-hole and no yielding of stitch. The suture material all passes away, leaving no foreign body. Diaphragm formation, an inevitable result of every method which adheres to the principle of seroserous apposition, is minimized and post-operative adhesions are greatly diminished.

Human Placentation.—Embryology is always instructive and at times of medico-legal importance, especially such features as pertain to placentation as indicating best the age of the fetus. The following are the latest observations of the second stage of human placenta-formation, according to C. Van Tussenbroeck (*Zeitschrift f. Geburtsh. u. Gyn.*, 1901, B. 45, H. 3): (1) The metamorphosis from the primitive to the discoid placenta occurs at or about the sixth month of gestation. (2) The necrosis of the decidua is the effect of mechanical pressure. (3) The reduction of the tufts on the part of the reflexa is in consequence of the obliteration of the spaces between the chorion and the reflexa. (4) The circulation in the vitelline membrane does not in man have any contact with the chorion. (5) At the sixth month when the transition to the discoidal placenta occurs, the decidua reflexa is totally obliterated. (6) The increase in the area of the placenta occurs by a displacement of the reduplication fold of the decidua reflexa. When the functions of the decidua are ended and the chorion has united with the decidua vera, the growth of the serotina occurs step-by-step with that of the uterine wall. (7) The cotyledons arise from the fact that the outer covering of the serotina offers an unequal resistance to the expansion of the fetal placenta. This resistance is greatest where the uteroplacental arteries run and make there rather fixed points. For this reason the arteries come to lie in the apex of the cotyledons or in the redundant part of the septa between the cotyledons, while the venous structures, being the less resistant, are found at their bases. This arrangement determines fixedly the direction of the placental blood-current. (8) The cortex of the tropoblast described by Siegenbeek Van Henkelom is easily recognizable in the half-developed placenta and distinguishable from the decidua upon which it rests. (9) The "stalk-tufts" (*Haftzotten*) are not in the decidua but in the cortex of the tropoblast. (10) The obliteration of the cell-layer of Langhans takes place by a pushing of these cells between the syncytium. This cell-layer appears to serve only in completing the tissue for the syncytium.

Cystitis, Pyelitis and Pyelonephritis in Women.—Medical literature scarcely affords a more complete account of clinical and bacteriological findings in cases of inflammation of the urinary tract in women, than is presented by T. R. Brown (*Johns Hopkins Hosp. Reports*, Vol. X., Nos. 1-2, 1901). The commonest cause of these infections in women is the bacillus coli communis, which sets up an acute inflammation without the aid of any other micro-organism. Other micro-organisms frequently found are the tubercle bacillus, various staphylococci and the bacillus proteus vulgaris. The proportion of cases due to the bacillus coli communis is greater in women than in men, probably owing to the proximity of the female urethra to the anus. Accessory etiological factors are anemia, malnutrition, trauma of and pressure on the bladder, congestion of the bladder and retention of urine. The bacteriological findings suggest certain therapeutic measures. The urine will probably be a poorer medium for the growth of bacteria, the lower the specific gravity and the less the amount of albumin and of urea present; hence water should be given in large amounts. This

treatment has the additional virtue of flushing out the kidneys and bladder and getting rid, as far as possible, of collections of purulent matter. Urotropin, cystogen, salol and similar antiseptics are of great value in acute infections, although of much less value where the condition has become chronic. If the urine be alkaline, administer substances tending to render it acid, as boracic, benzoic, or camphoric acid; while in those cases where the urine is acid alkalies should be given (as bicarbonate of soda or citrate of potash), the reason being that the urea-decomposing micro-organisms have their growth hindered by the pressure of an excess of acid, while micro-organisms which retain the acidity of the urine have their growth inhibited by an alkaline condition of urine. Correction of disorders of nutrition or digestion is important. Other useful measures are topical treatment, irrigations, instillations; operative treatment of various kinds may also be necessary.

Dilatation and Endometritis.—A logical and scientific parallel between abscess-cavities and discharging sinuses on the one hand and on the other hand simple chronic catarrhal or chronic purulent endometritis and obstructive dysmenorrhea is set forth by F. FRANKE (*Zeitschr. f. Geburtsh. u. Gynäk.*, 1901, B. 45, H. 3). In the former conditions the old surgical law is well established and obeyed, that free evacuation must be had and complete drainage maintained. In all the forms of endometritis free evacuation and complete drainage are the rational indications, because retention here means threatened or actual extension to the adnexa. In obstructive dysmenorrhea it is the very fact of the existence of an obstacle to the outflow of the blood and the clots which causes the pain. Franke seeks to apply the surgical law cited above to these gynecological conditions by inserting a rubber drain-tube into the uterine cavity well within the internal os, but not up to the fundus. Contact between the tube and the fundus, would result in troublesome contractions. After dilatation, which must be deliberately done, the tube is threaded over a sound and thus passed in. It is retained in situ by a couple of threads lightly caught in it and in the cervix uteri. Its bore must be free, to permit ready drainage, and its walls thick enough to be resistant. It can be retained in situ until the stitches cut through, under the usual precautions of antiseptic vaginal douches, and then replaced. Confinement to bed over the first few days is not essential. When a stenosis exists Franke resorts to twelve or fifteen small incisions around the entire periphery of the cervical canal, which permit of spreading without tearing and in healing are covered with mucous membrane, not scar-tissue and therefore do not contract again, perhaps to a higher degree than before the operation. In the cases he reports (two) results were permanent and without retrogression at the end of a year or more.

Tuberculous Rheumatism.—Various pseudorheumatic arthritic conditions are recognized in association with gonorrhea, scarlatina, typhoid fever, measles and diphtheria. Poncet proposed to classify as "tuberculous rheumatism" similar conditions due to tuberculosis. According to M. MAILLAND (*La Presse Med.*, Sept. 14, 1901), the term does not apply to ordinary cases of cold abscess in which the lesion is destructive, but relates to irritative conditions, of fibrinoplastic tendency, analogous to those of infectious pseudorheumatism, and clinically including forms which simulate every variety from simple arthralgia to complete ankylosis. The administration of salicylates is a waste of time in "tuberculous rheumatism." It should be remembered that in pseudorheumatic arthritis the maximum of pain is felt at the level of the joint itself, while in true rheumatism the painful spots are rather periarticular. In the presence of pseudorheumatism tuberculosis should be thought of, care being taken to exclude gonorrhea and acute infectious diseases as causative agents.

Otitis Media and Aphasia.—With the success of neurologists in fixing the various cerebral centers arises the relation between such centers and their connections on the one hand and on the other hand various diseases. No disease is any more significant than left otitis media purulenta, in the view of W. MERKENS (*Zeitsch. f. Chir.*, Aug., 1901), in its bearing upon speech-center disturbances. The chief considerations he sums up as follows: Abscess of the temporal lobe secondary to otitis media purulenta which causes speech-disturbances is only exceptionally a lesion of the true centers of speech. As a rule the interruption is only of the association fibers. First in frequency come those fibers which connect the sound-picture-center with the true perception-center. More rarely the break is between the sound-picture-center and the writing-center. The so-called optic aphasia belongs really under the head of psychical blindness and not to true aphasia, *i.e.*, speech-center disturbance. Temporal lobe abscesses often involve the life of the patient, hence early diagnosis and correct localization are essential. No symptom is more important than signs of aphasia, but these must be unmistakable in themselves and directly an issue of the disease. The surgeon must determine whether the speech difficulties began definitely with the other symptoms of the disease or were directly associated therewith. The first important feature is whether the patient can give undisturbed utterance to his own concepts and perceptions by always readily and precisely selecting and uttering the suitable words. This is most of all important with reference to the expression of his own subjective mental processes. Next, he must test the subject's understanding and reception of loudly spoken language. Finally he is concerned with the reception, understanding and expression of writing. If disturbances of the writing-center are present and especially if psychical blindness is associated with it the site of the abscess is probably rather posteriorly situated in the temporal lobes.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, OCTOBER 26, 1901.

THE SMALLPOX PROSPECT.

Recent reports of the United States Marine-Hospital Service show that, so far as smallpox is concerned, we are about to enter upon the colder weather in this country under unfavorable conditions. Smallpox is recognized generally as almost exclusively a winter disease. The advent of warm weather almost always brings with it a marked reduction in the epidemicity of the disease and often summer completely obliterates it even where it has been raging with special virulence. Whether cold actually fosters the growth of the smallpox germ, while warm weather inhibits it, can not be definitely determined until the microbic cause of the disease is isolated. There are those who insist that the real factor in the increased virulence of smallpox in winter depends on nothing more than the fact that the poor, among whom smallpox is especially prevalent, live closer together and with less ventilation in cold weather.

Ever since the Spanish-American War and, as pointed out by Dr. Nevins Hyde in a recent number of the *Popular Science Monthly*, as a direct consequence of it, we have not been without a disquieting number of smallpox cases in this country. Each winter for these last three years has seen the disease acquire virulent form. Each summer has seen considerable diminution of virulence. At the beginning of winter for three years past there have always been enough scattered foci of smallpox to insure the wide spread of the disease during the cold months. The reports of the disease for the present autumn, far from being exceptional in this respect, are distinctly alarming. The smallpox scare of last year led to the vaccination of a large part of the population, but the disease still finds susceptible subjects in abundance. In very few parts of the country do the Marine-Hospital statistics show a less number of cases during July, August and September than during the corresponding period of last year.

This incidence of smallpox is not localized in the parts of the country distant from large centers of population, where the absence of public health regulations and legal quarantine might be thought to account for the prevalence of the disease. New York, Massachusetts, Ohio and Indiana show the existence of a number of cases of the disease and most of them are situated in large cities. Wisconsin, Minnesota, Colorado and Kansas, on the other hand, report large numbers of cases mainly from country districts. Louisiana and Texas are the only two States that show notable decreases in the number of cases of smallpox reported since July 1, 1901, when compared with the corresponding period of last year. The total number of cases reported to the Marine-Hospital authorities for these last four months throughout the country is nearly 10,000. During the corresponding months of last year the total number of cases was only a little over 4,000. With the unfavorable weather just opening up the prospect thus disclosed is not pleasant. It is true that some of the cases that help to swell the total in these reports occurred before the summer months, but this does not impair the comparative significance of the totals for the corresponding periods of the two years. If the vastly smaller number of cases reported last year foreboded, as we stated at the time, a serious outlook for the winter months, then the latest reports are indeed ominous.

Not a few of our Eastern cities report smallpox even during very recent weeks. The danger should be frankly faced and the general population safeguarded. Now is scarcely the

time to discuss the value of vaccination. That has been proved according to the best judgment of the vast majority of the serious scientific medical men of the world. Every possible means should be taken to secure universal vaccination.

As to vaccine virus a word of warning seems necessary. Only vaccine material of recognized quality should be employed and the physician should assure himself as to its source and the grounds for considering it of genuine efficacy. There is no doubt that some of the opprobrium cast upon vaccination and some support of the pretention of its inability to protect against smallpox has been due to the use of inefficient vaccine material. Another word of warning as to the condition of the tenement-houses in densely populated centers seems called for. Here it is in the crowded living-rooms of the poor that smallpox finds its favorite breeding-place. Here it acquires during the cold days, when ventilation is sacrificed to warmth, the virulence that gives it power to spread even in the houses of the well-to-do. From here especially come the school-children and the workmen who distribute the disease to many others. Present conditions cannot be changed at once, though fortunately the trend of modern rational philanthropy is in the direction of fundamental reform, in this matter. Special vigilance, however, can secure if not immunity from the disease at least freedom to a great extent from its most serious dangers. Now that smallpox is known to be imminent it will be criminal if foci of it through medical oversight or carelessness of boards of health are allowed to develop to dangerous extent before being properly recognized and broken up. We earnestly trust that our own New York City Board of Health will prove itself more capable in this regard during the coming winter than during the past.

NEW YORK STATE MEDICAL ASSOCIATION.

THE eighteenth annual meeting of the New York State Medical Association has continued the good work of recent years very creditably and has emphasized the renewed interest that the profession of New York City and State are taking in the local branch of the American Medical Association. To those who remember the small attendance at association meetings in Mott Memorial Hall only three years ago the present well attended sessions are a pleasant surprise.

This increased attendance deserves all the more to be a subject for congratulation as it doubtless portends the narrowing of the breach that has kept New York State from having and wielding her immense influence for the benefit of the medical profession in the national association.

The scientific program of the present session comprised some very interesting and practical features. Dr. Deaver's paper on appendiceal fistula with its warning that such unfortunate sequelæ are always due to delay in operating, aroused the usual discussion as to the possibility of ever treating the condition medically. It is evident that there are now but few even of general practitioners who have any confidence left in the power of remedial measures other than surgical to bring any lasting relief in appendiceal conditions. The symposium on cancer brought together a most interesting and suggestive collection of papers on this important subject. Dr. Blumer's review of the present status of the parasitic theory of cancer was a masterly bit of critical medical literature. Dr. Ewing's critique of statistics of cured cases of cancer that do not include details as to the previous clinical course of the tumor and the histological elements of which it was composed deserves widespread attention. The application of its suggestions would inaugurate a new and promising era in the clinical study of cancer. The symposium on arteriosclerosis presented very succinctly and practically the main features of an increasingly interesting condition.

In general the meeting was a very representative gathering of men of many minds in medicine. The program suffered somewhat in general interest perhaps because of the great preponderance of papers on surgical subjects. On this occasion of forty-eight papers a scant dozen were medical in character. The fault is of the times rather than the committee but its recognition and correction even to a limited degree would certainly be welcomed by the mass of attendants at medical meetings.

The dinner of the Association this year was made a very taking feature by an excellent toast list. The committee of arrangements deserves congratulations on their successful management of the details of the meeting. The association itself begins the new century with a very promising exhibit of union and strength.

RULERS AND THEIR MEDICAL ATTENDANTS.

"UNEASY lies the head that wears a crown." Uneasier still would seem to be the fate of those whom Fortune, with roseate promises of

fame and future success, picks out in emergencies to do surgical service for wounded or dying rulers. The experience of the last twenty years would justify a special invocation in the medical man's litany, "From attendance on persons in high political position, spare us, O Lord.'

The conditions in President Garfield's case were most sad. Only one of the attendants on the dying President is still alive. It does not seem too much to say that the lives of all of them were shortened by the worry of responsibility and the carping of popular misunderstanding. Their state of mind during their attendance on the President was anything but enviable. After his death their fees for service were disputed, criticized, delayed in Congress and finally paid most grudgingly. The practice of the chief attending physician was ruined and after a previous career, full of the greatest promise, he died almost in actual poverty.

The case of the Emperor Frederick of Germany, only a few years after President Garfield's death, was a repetition of the ungracious treatment of the medical men. There is no doubt that Sir Morel Mackenzie's life was shortened and its closing years tinged with bitterness because of the envious, contemptuous criticism that followed the Emperor's death. There were not wanting critics in France after President Carnot's death, a few years later, who did not hesitate to say that his life might have been saved or at least prolonged by more radical surgical intervention than was attempted. This, too, notwithstanding the fact that wounds of the liver, such as existed in President Carnot's case have always been considered as inevitably fatal.

It is not surprising, then, that the surgeons who attended our late President should be in no enviable position. The sad reflection with regard to all these cases is that the main part of the obloquy that falls upon inevitable results is due to the unthinking criticism of brother surgeons. Men who should realize sympathetically all the difficulties of the trying situation are the first to find fault with methods and details of treament of which everyone well knows they can understand very little at a distance. The critics are not so much the recognized quacks of surgical practice, for their opinion would have but little popular weight and no professional sting. It is supposedly reputable surgeons who assume an impossible omniscience *in distans*. Surely it is not too much to hope that progress in surgery and in culture, in ethical gentlemanliness and in brotherly fellowship will raise the medical profession above these lamentable persecuting methods. Medicine and even surgery, notwithstanding recent scientific advances, still remain arts and not true sciences in their practical applications. Failure of purpose, as the attainment of the ideal in any art, must remain inevitable under many circumstances. The last to condemn this sad incompetency of human effort should be those whose training fits them best to understand the liability to failure that the complexity of surgical and medical problems involves and whose personal experience has taught them that the most exhaustive knowledge of conditions does not guarantee against personal fallibility in what has been from earliest medical history and will remain the most difficult of all problems for the medical attendant—the question of prognosis.

The present lesson bears with it its weight of warning, however, not only for the medical attendants on those in high station, but for all however humble their conditions. There has always been and there persists a too great tendency to criticize "the other doctor" commonly on insufficient grounds. It is easy to criticize where all the conditions are not known and such criticism is not only unworthy but often eminently shallow and mistaken. The broader the mentality, the less the tendency to this thoughtless, merely carping criticism. Let us hope that the breath of culture that comes with more liberal education will bring an end to this undesirable state of affairs before the close of our generation.

A CHAIR CF SYPHILIS AND WHAT IT SHOULD MEAN IN OUR MEDICAL SCHOOLS.

Owing to the protean character of specific manifestations the habit of giving iodide and mercury "when in doubt" is very widespread among the profession. And it is probably better that several innocent persons should be mercurialized in this tentative fashion than that one luetic should be deprived of the benefit of specific remedies, but is it not a somewhat sad commentary on the so-called progress of medical science that the sum total of our knowledge regarding syphilis and its multiform lesions in skin and bone, viscera

and nerves, apparently is not sufficiently advanced to enable us at times to differentiate sharply between what is syphilitic and what is not?

Nearly every physician of even a few years' practice comes by hard experience to discover in what widely different ways the virus may make its presence known, but the acquisition of this knowledge involves the loss of valuable time and often the infliction of irreparable damage to the people who entrust themselves to his care. This infliction of damage we allege, of course, in a purely negative sense; referring to cases which, from ignorance merely, are allowed to progress from a frankly syphilitic to a para- or metasyphilitic—probably incurable—stage.

It sounds well to speak of tuberculosis and syphilis as the two great scourges of the human race, as in sad truth they are, but is there no better way to prepare men to cope with them than that now in vogue in our schools of medicine? With regard to syphilis we are decidedly of the opinion that there is.

The teaching of syphilis should not be a side issue in any medical curriculum. At present the student gets a little knowledge of it here, a little there and no very connected ideas of it anywhere. The avoidance of this not very praiseworthy condition of affairs calls for a concentration of knowledge. We suggest that the chair of syphilis should be exalted in our schools to the level and dignity of those which are now considered of paramount importance, and the man who would teach syphilis should know his subject root and branch. He should be as thoroughly familiar with its manifestations in brain and cord as in skin and bone, as a matter of fact—from the standpoint of importance—even more so.

To fill such a chair would require an exceptional type of mind, together with a peculiar training, and yet a kind of training that ought to appeal powerfully to a man who wished to advance the clinical side of medicine in a way fittingly analagous to that now adopted in pathology or bacteriology, for example.

Such a man must, to begin with, train his visualizing powers to a high degree, so that he may be able easily to evoke from his visual storehouse control pictures, so to speak, for contrast with what he has before his eyes in a given case. Furthermore, his knowledge of human nature must be intimate and far-reaching, his powers of observation nearly perfect. His preliminary clinical training should be general. With this he must acquire an intimate but selective knowledge of pathological processes, that is, a knowledge of the general and local workings of the poison of syphilis. And it goes without saying that his work in the pathological laboratory should cease only with his life's labors.

After his preliminary clinical training he should branch out into the at present somewhat narrow specialties of eye and ear, nose and throat, skin and nerves. From each of these he must glean everything which has an essential bearing upon his subject. To do this, time is the only requisite for the right man, and no greater time than we now give to the training of a pathologist or bacteriologist in the most limited sense of the terms.

With this broad training once attained, where can such a man find a place to put constantly into practise the knowledge he has acquired? Unfortunately we have no great hospital for syphilis like the St. Louis of Paris; and no city or general hospital could give to any one person the facilities which our ideally-trained man requires. In our judgment the most desirable places in the country for such practice are the great almshouses, many of which have already attained to the dignity of hospitals. Here one sees the scum of civilization, victims, to a large extent, of their own vices. Here syphilis flourishes and here it may be studied to the heart's content in every form under which it is known to make its hideous appearance.

It is in an institution of this sort that our professors of venereal disease should get their clinical experience, rather than in a dermatological out-patient department or in a surgical clinic.

Finally, when the happy time comes that the chair of syphilis is considered of tantamount importance to the others we have mentioned, and when it is occupied by a man trained as we have suggested, then and then only will students go away from our medical schools with an adequate appreciation of and ability to cope with a disease which, of all the ills the flesh is heir to, is the most virulent, insidious and deadly.

ECHOES AND NEWS.

NEW YORK.

Journal of Physical Therapeutics.—This new quarterly international review is to have an American editor in the person of Dr. Margaret A. Cleaves.

Electrotherapeutics.—This is the title of a new monthly journal to be devoted to the study of medical electricity and radiography. Dr. W. B. Snow is to be its editor.

The Craig Colony Prize for Original Research in Epilepsy.—Dr. Frederick Peterson of

New York offers a prize of $200 for the best original unpublished contribution to the pathology and treatment of epilepsy. Originality is the main condition. All manuscript should be submitted in English. The prize is open to universal competition. Each essay must be accompanied by a sealed envelope containing the name and address of the author and bearing upon the outside a motto or device, which is to be inscribed also upon the essay. All papers received will be submitted to a committee, consisting of three members of the New York Neurological Society, and the award will be made upon its recommendation at the annual meeting of the Board of Managers of the Craig Colony, October 14, 1902. Manuscripts should be sent to Dr. Frederick Peterson, 4 West Fiftieth street, New York City, on or before September 30, 1902. The successful essay becomes the property of the Craig Colony and will be published in its medical reports.

New York Academy of Medicine.—On Monday evening, October 21st, the Section on Ophthalmology held its first regular meeting. Dr. J. E. Weeks exhibited specimens of neuroma of the retina. Dr. A. Schapringer presented a case of amblyopia from inhalation of wood alcohol and Dr. H. H. Seabrook, a case of a peculiar neoplasm of the bulbar conjunctiva.

On Wednesday, October 23rd, the Section on Laryngology and Rhinology met. Dr. H. Holbrook Curtis read a paper on the "Early Appearances of Laryngeal Tuberculosis."

On Thursday evening at the meeting of the Section on Obstetrics and Gynecology, Drs. S. Marx, L. T. Lazinski and A. Brothers, presented specimens. Dr. S. W. Bandler read a paper on the "Etiology, Histology and Usual Course of Ectopic Gestation." This was discussed by Drs. E. H. Grandin, Bache McE. Emmet, S. Marx and others. Dr. C. P. Noble of Philadelphia then read a paper on "Extra-Uterine Pregnancy."

The following candidates for resident fellowship in the Academy were recommended for election: Drs. Fielding Lewis Taylor and Anna Wessels Williams.

PHILADELPHIA.

Leper in the City.—The ailment of Wing Ting Sing, a Chinese laundryman, has been pronounced leprosy and he has been placed in the Municipal Hospital. The disease first manifested itself in July, but only lately was its true nature revealed.

Foreign Surgeon Entertained.—Dr. Ernest Laplace gave a dinner of twenty-six covers at the Art Club October 17th in honor of Dr. Henri Hartman, the noted Paris surgeon, who is visiting the clinics of this city. The guests included the prominent surgeons of the city.

Smallpox.—For the week ending October 19th there were 69 new cases and 10 deaths reported, an increase of 9 cases and 8 deaths over the previous week. Dr. Martin, a well-known physician of Frankford, is suffering from the disease. Camden is building a temporary municipal hospital, 20 by 70 feet in size, in which to care for smallpox patients.

News From the Colleges.—The attendance thus far at the University of Pennsylvania, Medical Department, is 537, a slight decrease from last year. The freshman class is larger, however, showing a gain of 22 per cent. The Department of Dentistry also shows a decreased attendance. The course is to be lengthened to four years. A gratifying fact is the increase in college graduates among the matriculates, fully one-third of the medical freshmen possessing degrees.—Jefferson at present has a registration of 640, a substantial decrease from last year's figures.

Obituary.—Dr. Charles H. Voorhees, who died October 19th from apoplexy, was for many years a practitioner at Flushing, Ohio, where his practice was worth $30,000 per year. Of late years he has been attending traveling invalids, which capacity brought him to this city about one year ago.

Indiscriminate State Aid to Charities.—A feature of the recent State Convention of the Directors of the Poor and Charities of Pennsylvania at Altoona was the address of Cadwallader Biddle, of this city, General Agent of the Board of Public Charities of Pennsylvania. After giving the early history of State aid for hospitals and the springing into existence of new institutions tempted by the bait of State aid, he said: "The most serious act of all was that passed in the last session of the Legislature, by which the State accepted the Lackawanna Hospital in Scranton as a State institution and assumed the entire cost of operating it. Already inquiries are being made from every section of the State asking how this was accomplished and intimating that at the next session similar acts will be introduced for very many of the existing institutions. What argument can be raised against this? If the State maintains a general hospital in one section, should it not do so everywhere? All its citizens should be treated alike. This is equally true of orphan societies, homes for friendless, etc." Mr. Biddle's remedy is to treat hospitals for the sick and injured as those for the insane. When they have not a sufficient income from private sources they should be allowed for each patient a fixed amount from the State. The theory that the State must become the mainstay of every charitable institution is extremely pernicious and misleading. The limit of abuse in the distribution of State favors to charitable institutions has been reached when those which are not receiving sufficient local support pass into the absolute ownership of the State.

Licensing Nurses.—In an editorial the *Press* states that the formation of State Nursing Councils, as urged by Mrs. Fenwick, is indispensably necessary. After mentioning the discrepancies in the length of course, entrance requirements, and methods of training in the various hospitals of the city and the injustice to patients and physicians caused by inadequate training, it says: "In time these things right

themselves, because the young women who are so unfortunate as to attempt a short cut into the work of nursing discover after a few years that, while the nominal pay is high, the time for which a nurse insufficiently equipped is wanted is so short that the average wage of such a nurse will be considerably less than that which she would earn behind a counter. But in nursing, as in medicine, the State ought to step in and provide a State Nursing Council and establish rigid qualifications which would give a license precisely as is done in medicine."

Death of a Pioneer Woman Physician.—Dr. Hannah E. Longshore, the first woman to practise medicine in this city, died October 18th at the age of eighty-three. She was one of the ten members of the first graduating class of the Woman's Medical College of Pennsylvania and was for a time demonstrator of anatomy in that institution. When she put out her sign as a medical practitioner she met with sneers and ridicule. Male physicians refused to consult with her, druggists refused to fill her prescriptions, and teachers in the public schools instructed their pupils not to walk with Miss Longshore "because her mother was a 'woman doctor.'" But her practice increased to such an extent that after forty years of activity she retired with a modest fortune, it being said that her practice was larger, with one exception, than that of any other woman physician in the United States.

CHICAGO.

Diphtheria.—The spread of diphtheria in the Humboldt Park district still continues, but the diphtheria mortality remains remarkably low, owing, it is believed, to the general and intelligent use of the antitoxin by Chicago physicians.

Officers of the Chicago Gynecological Society.—At a meeting of this Society, held October 18, 1901, the following officers were elected: President, Dr. L. E. Frankenthal; First Vice-President, Dr. A. H. Ferguson; Second Vice-President, Dr. Junius C. Hoag; Secretary, Dr. William H. Rumpf; Treasurer, Dr. Emil Ries; Pathologist, Dr. M. L. Harris; Editor, Dr. Charles S. Bacon.

Chicago Surgical Society.—At the annual meeting, held October 17th, the following officers were elected: President, Dr. Christian Fenger; Vice-President, Dr. John B. Murphy; Secretary, Dr. A. E. Halstead; Treasurer, Dr. D. N. Eisendrath; Council, Drs. E. Wyllys Andrews, John B. Murphy, and L. L. McArthur.

Chicago Medical Society.—At a meeting held October 16th, Dr. William J. Butler showed an interesting case of congenital heart lesion in a boy, seven years of age. The apex of the heart was seen while the child was in the erect position in the fifth interspace, inside and extending to the mamillary line. Palpation confirmed this location of the apex, and one feels not only the heart impulse, but also a systolic thrill which becomes more pronounced toward the base, reaching the maximum in the third interspace over the second rib and in the second interspace close to the sternum. On percussion the upper border of the heart begins in a relative dulness in the second interspace, which becomes absolute from the fourth rib. The right border of the heart is found two fingers' breadth to the right sternal border. On auscultation from apex toward the base a loud, rasping systolic murmur is heard obscuring the first sound. This murmur reaches its greatest intensity in the third interspace over the second rib, and in the second interspace to the left of the sternum, coinciding perfectly with the localization of the systolic thrill. The murmur is transmitted in every direction and heard over the back. The second sound is distinctly heard over the entire heart. The most interesting feature of the case, and the one which would, without examination, cause doubt as to the diagnosis made, is the absence of cyanosis. The author is convinced that cyanosis is not a necessary factor in the diagnosis of such cases. The author has seen six congenital heart lesions in the past five years. The three first cases were all pulmonary stenosis. One of them was intensely cyanotic. Another suffered from chronic stasis, and presented a cyanotic icteroid hue. The third case was a pale-faced girl of seventeen years. The mucosæ were slightly cyanotic. Of the cases seen here, one was a mitral and aortic lesion, the postmortem examination having been made by Dr. Hektoen, and the case reported by Dr. Cotton. The other two, of which this is one, were pulmonary stenosis. The first case was a pale-faced lad of eleven years, who appeared at the clinic two years ago. This boy died later. A postmortem examination was made and confirmed the clinical diagnosis.

Fears the Spread of Smallpox.—Chief Medical Inspector Heman Spalding is watching the development of smallpox in the outlying towns. He has made personal visits to Michigan City, Ind., and Harvey, Ill., where the disease exists, and has secured the cooperation of authorities in those towns to prevent its spread. Health Commissioner Reynolds fears some trouble with smallpox this winter, because of its prevalence throughout the country. He is therefore taking all possible precautions to prevent its advent in Chicago.

To Examine the Brain of Frank Collier.—It is said that pathologists throughout the country, as well as anthropologists and the medical profession generally, are awaiting with special interest the examination of the brain of the late Frank Howard Collier, the attorney whose death at the Cook County Hospital last August followed several years of intermittent attacks of insanity, traced to a blow on the head received during a political campaign. The brain will be examined by Drs. Ludwig Hektoen, E. C. Fortner, E. R. Le Count, and E. M. Brown. It is now in the laboratory of Rush Medical College, and the result of the examination will be announced at as early a date as practicable. Professor Starr, the anthropologist of the Uni-

versity of Chicago, will also watch the investigation, and make a report in regard to the case.

To Lay Cornerstone of Hospital.—There were elaborate exercises and a great parade of Catholic societies Sunday, October 20th, at the laying of the cornerstone of St. Anne's Hospital, an institution for consumptives to be erected by the Sisters of St. Elizabeth's Hospital. We have already referred to this hospital in previous issues of the Medical News. When completed, the hospital will cost $150,000. Although it is built by Catholics, patients of any religion will be admitted to its wards, and if unable to pay a fee the treatment will be gratuitous. Bishop Muldoon officiated at the exercises.

Surgery of Pulmonary Abscess, Gangrene and Bronchiectases Following Pneumonia.—At a meeting of the Chicago Medical Society, held October 9th, Dr. Daniel N. Eisendrath contributed a paper on this subject. After going into the literature in a very exhaustive manner, he drew the following conclusions: (1) Both acute and pulmonary abscess and gangrene following pneumonia may develop immediately, and chronic and simple putrid abscesses, with or without bronchiectases, are more remote sequelæ of both croupous and influenzal pneumonia. (2) The most valuable points in the history are the etiology; the sudden expectoration after an apparent crisis of pure non-odorous pus in the simple abscess cases, or of fetid pus in the gangrenous variety. In the chronic cases there is usually a history of a pneumonia having preceded the condition at some considerable time previously, followed by expectoration of large quantities of pus, with exacerbations of fever, accompanied by emaciation and frequently clubbed fingers, etc. (3) Signs of cavity are seldom present. The moist râles, especially of large metallic character, are the most reliable physical signs. The character of the sputum is also of great value, whether purulent or fetid. Elastic fibers are more frequently found in gangrene than in abscess, being comparatively rare in the latter. (4) The X-ray is only of confirmatory value, as it shows chiefly thickened areas of lung, and should not be absolutely relied upon. When it shows a shadow at the same point where the physical signs are present, it is of value. (5) The prognosis of abscess and gangrene following pneumonia, medically treated, is not very favorable. Many cases of both varieties can be successfully treated in a surgical manner by pneumotomy. One of the greatest difficulties is the exact localization of the focus. The statistics which I have gathered show a marked increase in the percentage of recoveries, especially in the cases which have been reported within the last five years, over that of the preceding five or even ten years. The prognosis for the chronic cases is not so favorable. The patients are usually operated upon when in an emaciated condition, and the walls of the cavity are often rigid, so that they do not contract well after being drained, and the free communication of a bronchus with such cavities is also a great barrier. But statistics in this variety are also improving, especially when combined with excision of the affected portion of the lung.

Typhoid in Chicago.—The weekly bulletin of the City Health Department, issued October 14th, calls attention to the unusual prevalence of typhoid fever throughout the country. Commissioner Reynolds urges increased caution in diet and in the use of untreated hydrant water by the young and non-immune, and calls upon physicians to have the diagnosis of the disease confirmed by bacterial examinations in the department laboratory. These examinations, he states, will be made and reported upon promptly by telephone without charge. Typhoid fever is more prevalent in Chicago than it has been at any previous time since the Health Department began to make records. The record here shows that the typhoid mortality for the past three months is four times what it was during the corresponding quarter last year. In the record of typhoid mortality, Chicago for the third quarter of the (July, August, and September) year shows an increase of 273 per cent. over that of the first six months. The average autumnal increase in this region is about 70 per cent., so that Chicago's full increase this year is very nearly four times greater than usual. There is no obvious local cause during the third quarter for this excessive increase. It is true that the first six months of 1901 were dryer than usual. Up to the close of June there had been 5.4 inches less rain than the average since 1871, and the ground water was correspondingly lowered. But it is not yet conclusively proved that the stage of the ground water affects the prevalence of typhoid, and it is less likely that it should do so in Chicago, with its water supply direct from the lake. Finally, the exhaustive studies of the department fail to reveal any connection between this increase and either the milk or the ice supply of the city.

Chicago Academy of Medicine.—At a meeting, held October 11th, Dr. W. G. Stearns reported an interesting case of fracture of the inner table of the occipital bone with cerebral concussion and contusion involving the base of the temporo-sphenoidal and frontal lobes. Dr. L. E. Schmidt spoke on the necessity of a clear diagnosis in operations on the prostate.

GENERAL.

Medical Society of City Hospital Alumni, St. Louis.—The Society met in the amphitheater of the City Hospital Thursday, October 17th. The following papers were read: The Bladder in Its Relation to Pelvic and Abdominal Surgery, by T. C. Witherspoon; Report of a Case of Appendicitis in a Patient Having Transposed Viscera, by W. C. Mardorf.

Malaria and Cancer.—According to press despatches, injections of malarial blood as a cure for cancer are proposed by Professor Frederick Loeffler. Finding that amid trop-

ical conditions most conducive to malaria cancer is of extreme rarity, he was led to the conclusion that when malaria is administered as a therapeutic it acts as a antidote to cancerous disease. What he calls the remarkable infrequence of cancer among negroes in the United States and other African populations is cited as one of the chief supports for his theory. In an interview he is reported to have said: "Realizing that malaria is capable not only of infecting the human system, but occasionally of counteracting the ravages of other diseases, the idea occurred to me of attacking cancer by the aid of malarial poison. It is established that malaria, when artificially produced by hypodermic or internal injections of the blood of malarial patients, can be arrested by prompt administration of quinine. Accordingly, I suggest the inoculation of cancerous persons either with mosquito poison or the blood of patients afflicted by other malarial infections. Previous attempts to cure cancer through vaccination with infectious substances have not only been crowned with little success, but have been accompanied by great danger, because of inability to control the antidote. In tropical lands where malaria flourishes cancer is seldom known."

Curious Death.—The doctors in Vienna, according to the daily press, have been made interested in the case of a young man, twenty-three years old, who has just died after a six months' painful illness, which puzzled the physicians, including German specialists. Shortly before his death his ailment was diagnosed as the result of the hatching of eggs of a blue bottle fly, which the patient had swallowed, causing perforation of the intestines. The sufferer was then too weak to undergo an operation. An autopsy confirmed the diagnosis. Part of the large intestine was riddled.

Ohio Valley Medical Association.—The following invitation is given by this society:

" 'The time has come, the doctor said,
To talk of many things:
Of bugs and bones and cases rare,
Of babes and other things.'

"Know All Ye Disciples of Esculapius by These Presents:

"That on the eleventh and twelfth days of the eleventh month, in the year one thousand and nine hundred and something or other, in the city of Henderson, State of Mint Julips, otherwise known as old Kaintuck, on the banks of the Ohio, and near several other Banks, there will be convened an assembly of practising doctors, that is, they are always ready to practice, *nolens volens,* at the bar, table, or at the bedside: whether it be to help make the issuance of Leah's fruitful womb painless, or to demonstrate the dissection of spring chickens; and as the story goes, they will meet together for the purpose of mutual pleasure and improvement. We purpose to have a good program on subjects of scientific nature, by practical physicians, who have toiled through the Wilderness of Endeavor, toward the Promised Land of Success.

"It was the historian Froude who wrote, 'The knowledge that a man can use is the only real knowledge; the only knowledge that has life and growth in it and converts itself into practical power. The rest hangs like dust about the brain or dries like raindrops off the stones.' The object of the founders of this Association was to create a live, practical organization of working physicians. The success of their effort has been proven in the past three years, for Know Ye, by this Greeting, that this Association is now in its third or tertiary stage, having been delivered at Sturgis, Union county, Kentucky, in August, 1898, and has now merged from twenty members to nearly two hundred. Has passed through the stage adolescence, and on the 13th of May, 1901, was raised to the third degree, and ordained, specified, rechristianed the "Ohio Valley Medical Association." You are cordially invited to attend and take part in the proceedings."

Ohio Valley Medical Association.—Partial program is as follows: Treatment of Pneumonia, Douglas C. Ramsey, M.D., Mt. Vernon, Ind.; Modern Surgery of the Gall Bladder, by H. Preston Sights, M.D., Paducah, Ky.; Clinical Microscopy, Its Value and Limitations in Private Practice, by Charles W. Hartloff, M.D., Evansville, Ind.; Plastic Surgery of the Face, by M. F. Coomes, M.D., Louisville, Ky.; Puerperal Convulsions, by T. J. Townsend, M.D., Owensboro, Ky.; A Few Things I Know, by Henry T. Dixon, M.D., Evansville, Ind.; The Endometrium, J. A. Humphrey, M.D., Henderson, Ky.; Treatment of Infected Wounds of the Hand, by Horace Whitacre, M.D., Cincinnati, Ohio; Carcinoma of the Breast, by Robt. H. Moss, M.D., Niagara, Ky.; Inguinal Hernia: Bassini's Operation for Radical Cure: Report of Cases, by W. A. Quinn, M.D., Henderson, Ky.; A Further Study of Strontium Salts, by Leon L. Solomon, M.D., Louisville, Ky.; Medical Treatment During Period of Adolescence, by S. S. Amerson, Sullivan, Ky.; On Pediatrics, by C. C. Lewis, M.D., Owensboro, Ky.; A Few Practical Points on the Diagnosis and Treatment of Syphilis, with Lantern Slide Illustrations, by M. L. Heidingsfeld, M.D., Cincinnati, Ohio; A Plan of Campaign, by W. J. J. Paris, M.D., Marion, Ky.; The Use of Normal Salt Solution, by C. H. Todd, M.D., Owensboro, Ky.

Assistant Surgeon at the Freedmen's Hospital.—The United States Civil-Service Commission invites attention to the fact that the examination announced for October 29-30, 1901, to be held in any city in the United States where postal free delivery has been established, for the position of assistant surgeon at the Freedmen's Hospital, is postponed to November 12-13. (See MEDICAL NEWS, Sept. 28, p. 508.)

Longevity in the United States.—In line with a recent editorial on "Longevity and Life Insurance" in the MEDICAL NEWS, an editorial analysis of the recent Census Bureau Statistics given in the *New York Tribune* is of interest. "A bulletin has just been issued by the United States Census Bureau in which a comparison is made between the death-rates in this country for 1890 and 1900, and it may be confidently asserted that few statistics published by that branch of the government possess such a gratifying character. It appears that there was a falling off of nearly 10 per cent. in the proportion of deaths to population during the last decade of the century just ended, while the average age at which Americans now die is put at 35.2 years, as against 31.1 in 1890. A gain in longevity of 13 per cent is here indicated. At first the announcement seems a little incredible. The figures hold good, however, only for cities of eight thousand inhabitants or more, and hence are in one sense partial. It is doubtful if the improvement has been so rapid in the rural regions. Still, if the conditions of city life are here accurately represented there is certainly occasion for profound congratulation.

"Analysis of the bulletin here referred to shows, moreover, that 'the great white plague,' which for so many years claimed more victims than any other malady, no longer stands at the head of the list. The death-rate from consumption was 245.4 for every 10,000 persons in 1890 and only 190.5 in 1900. No other disease shows such a great falling off, although diphtheria and bronchitis, cholera infantum and the diarrheal disorders of adults, general debility and typhoid fever, closely approach it. For most of these changes it is easy to find some explanation in the improved sanitation of cities and greater painstaking with food and water supplies. But other influences have unquestionably operated in two instances. Consumption is now dealt with more effectively than ever before, because the fact that it is often curable is recognized. And Behring's antitoxin, which is scarcely ten years old, perceptibly restricts the ravages of diphtheria.

"Unfortunately, however, there are a few maladies which show an increased mortality. From pneumonia there were 191.9 deaths among every 10,000 people in 1900 and only 186.9 in 1890. The difference is slight, but it is sufficient to put this disease slightly ahead of consumption as a destroyer of human life. Here again it is not hard to find a reason for the change. It is scarcely a dozen years since what is now known as influenza invaded this country. The census bulletin shows that the deaths directly assigned to it rose from 6.2 in 1890 to 23.9 in 1900. But the effects did not stop there. Pneumonia is one of the most common sequels of the grip, and often begins its demands on a patient's vitality when the latter is already pretty well exhausted. Thus the chances of recovery are materially diminished. But for this new complication it is possible that pneumonia, like consumption, diphtheria and bronchitis, would show an appreciable falling off in its havoc.

"The other maladies the death-rate for which has grown to a notable degree are cancer, apoplexy and derangements of the heart and kidneys. So imperfectly is the origin of the first of these ills understood that it is difficult to conjecture why its activity has been enlarged. But one cannot avoid regarding the increased proportion of deaths from the other causes here referred to as indications that the high pressure life of cities is proving more exacting than ever before. Business and social demands, excitement of one form or another, high living and lack of exercise work out their legitimate results in spite of the best efforts of the doctors. Nor will the best of general sanitary measures make any difference with these particular disorders. Evidently if any check is to be put upon mortality from them the people must apply it themselves."

Gen. Sternberg's Report.—Surgeon-Gen. Sternberg, in his annual report to the Secretary of War, makes the following observation among others on the health of the army: "The health of the army must be regarded as having been unusually good during the calendar year 1900. The admission rate for all causes in the army, volunteers and regulars, with a mean strength of 100,389 in 1900, was 2,311.81 per 1,000 of strength, as compared with 2,178.06 in the previous year; but during the year 1899 only 39,280 men out of a total of 105,546 were serving in the Philippines, while during the past year 66,882 of a total of 100,389 were thus serving. This is an important point to remember in considering the sick rates of the two years. The death-rate in China was large, 47.76 per 1,000 of strength, 23.62 from disease, and 24.14 from injury. From the close of the calendar year 1900 to the latest reports, the health of the troops in the Philippines had been steadily improving. Smallpox, so prevalent and deadly in the early occupation of the islands, has been almost entirely suppressed. Dysentery, constituting 13.44 per cent. of all cases of sickness, is the dangerous disease. The health of the troops serving in Cuba was excellent during the year. The medical record of the troops in Porto Rico for the year 1900 is an excellent one, comparing favorably with that of troops serving at the home stations. Referring to alcoholism in the army, Gen. Sternberg says: "The steady decrease of late years in the admissions for alcoholism among the men of the Regular army is a matter for congratulation. Military officers may be said to be unanimous in their opinion that this was mainly the result of the establishment of a post exchange, or canteen, at military posts. There is less drunkenness among troops in active service than in a command doing garrison duty in time of peace. In the Philippines during the past year the admission rate for alcoholism among the volunteers was 8.68, and for regulars 12.41; for troops in China, 7.70. These statistics do not sustain

the newspaper reports of drunkenness among the troops in the Philippines. In fact, medical officers report the habits of the enlisted men in the Philippines as very much the same as in the United States." Dr. Sternberg is to be congratulated on this full and vigorous report.

Obituary.—Dr. Henry R. Rogers, one of Dunkirk's most prominent citizens and the oldest physician in Chautauqua County, N. Y., died at at his home in Dunkirk last week after a short illness. Dr. Rogers was born in Winslow, Me., in 1822, and was a graduate of the Jefferson College in Philadelphia. He became distinguished for his scientific investigations and his original views of matter and the laws which govern it have attracted the attention of scientific men. His theory was that all physical phenomena, without exception, are transformations of electrical energy. His articles on astronomy and physics have had a wide circulation both in the United States and Europe and have provoked much discussion. He was a member of the Chautauqua County Historical Society, the New York State Medical Society, the American Medical Association and the American Association for the Advancement of Science. He abandoned the medical profession some years ago to devote all his time to literary work.

Dr. Joseph Sanders died at Oil City, Pa., last week at the home of his sister, from typhoid fever. He was thirty-four years old. He was graduated in 1892 from Bellevue Hospital Medical College, and then studied at Heidelberg, Berlin, Vienna and Leipsic, where he made a specialty of the diseases of the nose, ear and throat. Since 1895 he had practised in New York, and at various times was officially connected with Bellevue Hospital and the New York University. At the time of his death he was assistant chief of the Nose, Throat and Ear Dispensary of Mount Sinai Hospital. He was a member of the Academy of Medicine, County Medical Society, and the German Medical Society, of this city.

Charles Henry Brown, M.D., for many years managing editor of the *Journal of Nervous and Mental Diseases,* the official organ of the American Neurological Association, and the New York, Philadelphia, and Chicago Neurological Societies, died October 15, 1901, in New York City. Dr. Brown was born in New York June 18, 1856, and has always been a resident of this city. He was a graduate of New York University, class of '79, in which he took the highest honors. Dr. Brown was a son of Dr. Henry Weeks Brown, who died in 1864, and a grandson of Dr. Stephen Brown, a well-known physician of early days in New York, a contemporary of Dr. Alfred Post and Martyn Paine. During his life Dr. Brown was connected with the New York Dispensary, the Post-Graduate, and the Presbyterian Hospitals and the outdoor work of Bellevue Hospital. He was a member of the New York Academy of Medicine, the County Medical Society, the American Neurological Society, and the New York Neurological Society. He had been a member of a number of the most prominent societies in the city. He is survived by a widow and two daughters.

CORRESPONDENCE.

THE ROCKEFELLER INSTITUTE.

To the Editor of the MEDICAL NEWS:

DEAR SIR: The Milk Commission of the Medical Society of the County of New York regret that in the report recently published a wrong impression was inadvertently conveyed which, in justice to the Rockefeller Institute and to themselves, they would like to correct. The Milk Commission during the past year has interested the dealers and the medical profession in certified pure milk, and in the furtherance of its aims has been permitted to use certain data gathered by special workers of the Rockefeller Institute in pursuit of an independent investigation of a wider scope which the Institute has undertaken. The data gathered for the Institute which the Milk Commission especially made use of in the report referred to was in part bacteriological; while the results of farm investigations and the observations indicating the co-relation of improved sanitary conditions of the dairies with improvement in the character of the milk were derived almost wholly from an investigation, as yet unfinished, which is being carried on by Dr. Belcher, under the auspices of the Rockefeller Institute.

ABSCESS OF THE ANTRUM OF HIGHMORE—RAPID RECOVERY FROM ECLAMPSIA.

HERSCHEL, at the Verein der Aerzte in Halle A. S., June 5, 1901, read an exhausitve contribution on the subject of purulent inflammations of the antrum of Highmore. Anatomically the wall of the nasal cavities (outwardly) and of the antrums (inwardly) are identical and the hiatus semilunaris has two layers of mucous membrane, one on each bone surface and continuous one with the other. This arrangement accounts for the ready frequency with which this hiatus closes. Zuckerkandl found in fully ten per cent. of all cases that auxillary communications between the nose and the maxillary sinus are present. This fact must also be borne in mind in etiological and therapeutic considerations. Excepting occasionally pure trauma as the cause of disease at this point, all of the inferior diseases may present it as a complication, especially croupous pneumonia, typhoid fever, diphtheria, scarlatina, measles, influenza. Any ordinary

severe acute nasopharyngitis may extend directly into it and then pus supervene. Bacteriologically, all the germs characteristic of the above diseases have been found abundantly in the pus, and in addition streptococci in relation to facial erysipelas. Since erysipelas of the face commonly begins in lesions about the nose, it is fair to assume that in such cases it is the primary disease. Mechanically, these processes either extend directly or infectious material is forced into the antrum by hard blowing. Tooth-fangs may actually project into it or by a very delicate septum be separated from it. In either case a suppurating root may quickly infect the cavity. The processes are either acute or chronic catarrhal, and acute and chronic purulent inflammation, each with its own usual lesions and exudates. A hyperplastic type of the disease is also found, which may go on to the formation of cysts. In the more favorable purulent cases, the exudate is a muco-purulent one, in the less promising it is purely purulent which would go always with profound changes in the mucosa, such as polypi, cysts, ulcers, bone-caries, etc. Zuckerkandl claims that he has found true bone-changes far more rare than most rhinologists represent. Bone-plaques have been found in the cavity produced by a chronic periostitis and very likely the origin of the osteomata found in this cavity have at times the same origin. Rare but still rather common are profound bone-changes with necrosis and sequestration. The symptom complex is really most variable. Fever occurs with the acute disease and with exacerbations of the chronic form. Pain sharp and lancinating or dull and heavy is usually present, seated over the frontal process of the bone or in some of the teeth and due to irritation of the infra-orbital nerve. Occasionally by radiation and reference the supra-orbital nerve shows pain and one might think of empyema of the corresponding frontal sinus. In chronic purulent inflammation, we have the pain duller and usually more extended. Whether any causal relation exists between such inflammation and migraine is still not determined. Hyposmia and perversions and hallucinations of smell occur. The crucial symptom is the flow of pus especially forward out of the nostrils, usually colored with blood, intermittent or almost constant in flow, commonly fluid, often forming dirty scabs. Sometimes polypi change its course backward into the pharynx, or it reaches there through various auxiliary foramina. Thence the upper and later the whole respiratory tract may become involved and also the digestive apparatus. Ordinary sequelæ of the pus-flow are ulcers of the nasal mucosa, eczema of the skin about the nose, and later a putrid ozena with its usual scabs and scales. Later as ultimate nasal lesions we have hypertrophic rhinitic with the formation of polypi, especially about the bulla ethmoidalis and the processus uncinatus. Various minor and major, chiefly reflex disturbances of breathing have been seen, and twice in literature an obstinate drowsiness, yielding only to evacuation of the pus, have been reported. In the diagnosis of this disease it must not be forgotten that frontal headache may be due to it as well as to trouble in the frontal sinuses. Likewise in the so-called nervous headaches the cause may lie entirely in the antrum. The crucial symptom is of course the dribbling of pus into the middle fossa of the nose, namely the frontal sinus through its infundibulum, the antrum of Highmore through its foramen maxillare, and the anterior ethmoid cells. When the pus dribbles from the frontal sinus, as a rule its flow is most abundant when the head is held in the upright position. At this moment the foramen maxillare is the highest point, with reference to its floor. As soon as the head is bent far forward exactly the reverse occurs. The pus flows rapidly out of the antrum, but remains held in the sinus, because the foramen of the antrum becomes its lowest point and because the mouth of the infundibulum becomes its highest point. The best test for diagnosis is to drive a trochar and cannula through the nasal wall of the antrum close to the flow of the nose and then aspirate. Caution must be taken not to use too much force and drive the instrument out in to the cheek. When this accident occurs, as a rule healing without complications occurs. As a rare anatomical anomaly the antrum may be divided into an anterior and a posterior half. If one be empty and the other full of pus, aspiration will often then fail to find pus. The translucency test must never be forgotten, objectively it gives a loss of light in the affected cheek and subjectively the patient perceives no light on the same side. Expective treatment rests entirely with ice in local application and attention to the various symptoms. Carious teeth must always be removed. The nasal douche cautiously applied will keep the nose clean. When radical measures are needed, aspiration or other means of evacuation must be undertaken. The best are (1) through the osteum maxillare or any of the accessory foramina, (2) drilling through the alveolar margin in the socket of the second bicuspid or first molar tooth, (3) exposure of and entrance through the fossa canina.

SOCIETY PROCEEDINGS.

NEW YORK STATE MEDICAL ASSOCIATION.

Eighteenth Annual Meeting, Held at the New York Academy of Medicine, October 21, 22, 23 and 24, 1901.

FIRST DAY—OCTOBER 21ST.

BUSINESS MEETING.

The principal business was the election of officers for the ensuing year. The following gentlemen were elected: President, A. A. Hubbell of Buffalo; Vice-President, W. H. Biggam of Brooklyn; Secretary, Guy Lombard of New

York City; Treasurer, E. H. Squibb of Brooklyn; Chairman of Committee of Arrangement, Irving S. Haynes of New York City; Chairman of Committee on Legislation, E. E. Harris of New York City; Chairman of Committee on Library, J. W. S. Gouley of New York City; Chairman of Committee on Public Health and Medical Charities, Alexander Lambert of New York City; Chairman of Committee on Publication, Dr. J. Riddle Goffe of New York City; Delegates to American Medical Association: E. E. Harris of New York City; E. D. Ferguson of Troy; C. A. Wall of Buffalo; Chas. E. Quimby of New York City; H. O. Arrowsmith of Brooklyn.

SECOND DAY—OCTOBER 22D.

The *President,* John A. Wyeth, M.D., *in the Chair.*

Osteitis of Knee.—Dr. Wisner R. Townsend of New York City read the first paper, the subject of which was the correction of deformities following this condition. Dr. Townsend said that 50 per cent. of the cases of osteitis are followed by deformity where careful treatment is not pursued. The question is how to avoid the enormous number of almost useless limbs. All surgeons are agreed that there is no necessity for its occurrence, and that it is due either to faulty treatment, on the part of the surgeon, or failure of the patient to carry out the surgeon's direction. The amount of motion in a cured case will vary, but under the modern protective plan, the latest and best treatment, 95 per cent. of the patients should recover with useful and not unsightly limbs.

Subluxation of Tibia.—There are two conditions that cause deformity and useless limbs. These are subluxation of the tibia and another group composed of different complications. The principal complications are knock-knee, bow-legs and genu-recurvatum. For the treatment of subluxation of the tibia, the application of Billroth's splint is a very useful method, but it succeeds only in skilled hands. By the application of properly-directed pressure with section of the hamstring tendons correction of this condition can be accomplished gradually but successfully.

Ankylosis.—Where ankylotic conditions exist these may be broken up under narcosis, and then if they recur, as is not unusual, the limb will be in better position. Where ankylosis is broken up, however, the surgeon must be very careful to put up the limb in an absolutely correct position. For the treatment of ankylosis, excision is very rarely required. Osteotomy is a much more satisfactory operation. It produces less shock, because it does not inflict much injury on already diseased tissues and for the same reason it is followed by rapid healing. The small skin incision required gives very little chance for the development of sepsis. The manipulations required for the operation are not extensive, and this is also a preventive of septic complications. The failure to remove any portion of the bone does not give opportunity so usual in excision for interference with subsequent growth. The liability to bending, especially backward, common after excision, is also avoided.

Technic of Osteotomy.—The osteotome wound should only be of sufficient width to admit the instrument, which, as a rule, is less than one-half an inch across. The cutaneous incision for this purpose should be made longitudinally, and after the periosteum has been pierced the osteotome can be inserted and twisted around in such a way as to make the osteotomy on a horizontal axis. While excision destroys all possible hope of future motion in the joint, osteotomy leaves the possibility of a reasonably good joint with satisfactory motion.

Illustrative Cases.—Dr. Townsend gave details of two cases recently under his care. The first was a boy of sixteen suffering from marked genu-recurvatum. The bending back at the knee had begun about a year after excision of the joint, because of tuberculous arthritis and osteitis. A subcutaneous osteotomy was done and forcible straightening under ether was accomplished. The boy recovered with a good leg that continues to be useful and presents comparatively little shortening despite the previous excision. In the second case there was some subluxation of the tibia and flexion of the leg to an angle of 90 degrees. At first an attempt was made to straighten the leg under ether, but this did not succeed. A subsequent attempt succeeded to the extent of making the angular deformity only 125 degrees. Later the leg was straightened to 140 degrees. Finally a subcutaneous osteotomy was done with a straightening to 180 degrees. There is now very little difference in the length of the limbs and the patient is able to use the leg very satisfactorily.

Appendiceal Fistula.—Dr. John B. Deaver of Philadelphia said that this sequela of operation for appendicitis is an extremely important one. Its occurrence is always very annoying to the patient and detrimental to the credit of the attending physician and surgeon. It is besides not without its dangers and the means of avoiding it are extremely important. Its prevention would be easy if patients were operated on in the early hours of attack of appendicitis. If cases were presented for operation sufficiently early no fistula would exist. It is hard to understand why medical men insist on delaying operations in appendicitis cases, since there is more danger, not only at the time of operation, but also because of the sequelæ that are liable to develop if operation is done late.

External and Internal Fistulæ.—Fistulæ may be divided into two groups, external and internal. The latter group includes all those cases in which some means of communication is formed between the appendix and its broken-

down detritus and a hollow abdominal viscus, or, the more rare cases, in which there is a communication between the thorax and evacuation of the contents through the bronchial tubes. The most common internal fistulæ are those of the intestine. Fistulous connections with the ureter or bladder are, however, common enough not be unfamiliar. Internal fistulæ are rare as compared to external fistulæ. They also very rarely need surgical interference.

Intestinal Fistulæ.—It is sometimes thought that the fistulous connections between appendiceal abscesses and loops of the intestine form a not unfavorable termination of a case of appendicitis. There was a time when medical men looked upon this as a triumph of Nature's effort to cure the disease. As we have more carefully followed cases of appendicitis we have learned to realize that in these cases of intestinal evacuation of the abscess there are not infrequently subsequent symptoms of indigestion extremely obstinate to treatment, that are evidently due to the presence of this fistulous connection with a purulent focus. Undoubtedly, too, the adhesions which form because of the chronic inflammatory condition present furnish opportunity for the development of obstruction of the bowel. Dr. Deaver is sure that these old chronic sites of inflammatory disturbance often form the nidus in which cancer develops.

External Fistulæ.—These may be divided into two classes, fecal and non-fecal fistulæ. Through the non-fecal fistulæ there escape urine, pus, bile, or mucus. Urinary fistulæ in connection with appendiceal operations are usually due to some connection with the ureter. It is rather easy for this organ to become involved in the appendiceal condition at the point where it crosses the psoas muscle and so lies just beneath the appendix. Fistulæ discharging urine may, however, occur as the result of the ulceration of a suppurative appendix after adhesions of the bladder have formed. This will occur, of course, in cases where the appendix lies in the pelvis. In other cases, where the general direction of the appendix is towards the liver, the tip of the organ may contract adhesions to the gall-bladder. When suppuration or gangrene occurs, the gall-bladder may become involved and a true biliary fistula result.

Purulent and Mucous Fistulæ.—Where pus or mucus continues to come from a fistula there are usually some foreign bodies present as the exciting cause for the secretion. This foreign body may be the appendix itself, which has sloughed off during the acute process, but has not been discharged when the abscess was opened. As a matter of fact it is usually illusory to promise one's self that the appendix will slough away entirely under these circumstances.

Cause of Mucous Fistulæ.—Persistent mucous discharge from a fistulous tract will often be found to be due to the presence of a suture left during the operation or to some threads of gauze or other absorbable material that may be present. At times the basis of the fistulous discharge seems to be a microscopical opening into the lumen of the intestine. This is not large enough to permit of the passage of material amounts of the intestinal contents. There is not sufficient gas nor infectious material to give a distinctly fecal character to the fistulous discharge. There is, however, sufficient communication to keep up an irritative subinflammatory condition that renders the fistulæ permanent.

Fecal Fistulæ.—If all the contents of the bowel find their way through the opening left after an appendiceal operation, the patient is really suffering all the inconveniences of an artificial anus. If the opening into the intestines be high up in the small intestine, an amount of biliary matter may be discharged into the intestinal contents and this will prove very irritating to the skin. If the connection is with the lower bowel, very frequently the fistula will heal spontaneously. These ulcerative openings into the intestine are Nature's attempts to cure appendicitis, but Dr. Deaver has much less confidence in Nature than in the surgeon's knife.

Injury of Serous Coat.—Some of the fecal fistulæ that result are due to careless handling of the bowel during appendiceal operations. If, in the course of freeing adhesions, there occurs a tear in the serous coat of the bowel, this will frequently lead to a fecal fistula. The intestine derives most of its nourishment through the serous coat and the lessened nutrition at the point of injury, with infectious material on both sides of it, will almost surely lead to ulceration.

Treatment of Fistulæ.—Many of the fistulæ heal spontaneously if given a chance. The rule, then, is always to wait a reasonable time so as to allow Nature's therapeutic efforts to have their opportunity. There is one exception, however, to this rule. If the fistula has a connection in the upper part of jejunum then the nutrition suffers so much that an attempt must be made at once to close the fistula. Dr. Deaver has had a patient in whom the taking of milk was followed in five minutes by its appearance in the fistulous discharge. In order to encourage the healing of a fistula food should be given in concentrated form, so as to make the feces solid. Liquid material leads to a perpetuation of the fistulous opening. As a rule, no purgative should be given and the lower bowel should be cleared out by means of injections. These should not be given under pressure sufficient to appear at the fistulous opening.

Operative Interference.—It is important that the opening of a fistula should be made equal to the cavity which it drains at its widest

part. Some time this free opening permits of drainage and healing from the bottom. Where further operative interference is necessary the surgeon should cut wide of the fistula and work toward it, segregating the infected segment of bowel so as to avoid the development of peritonitis. As a rule, if the repair of the bowel would lessen its caliber very much, it is better to excise a portion of it. The severed ends should be brought together by suture, anastomosis being brought about without any chemical aid. Needle and thread are sufficient and these are always at hand.

Multiple Fistulæ.—It is important as a rule in operating for fistulæ to look for other openings into the bowel. A thoroughly successful excision of a portion of the bowel may be rendered entirely futile by the presence of another opening in the bowel which remained undiscovered at the time of the first operation. In these operations drainage is usually needed, though sometimes the surgeon may have confidence enough in the asepticity of the site of operation to close the abdomen thoroughly.

Prevention of Appendiceal Fistulæ.—The prophylaxis of these serious sequelæ depends entirely on the earlier recognition of acute appendicitis by the medical practitioner and the application of surgery to the case. When early operation is done no peri-appendicular inflammation develops, there is no involvement of the intestines nor of the bladder, ureter nor gall-bladder. Where these complications are not present it is practically impossible for the fistulæ to occur. A time will doubtless come when the medical profession will realize that it is almost criminal to allow a case to run until there is the possibility of such fistulæ developing as the result of negligence and timorousness in making the diagnosis.

Discussion.—In discussing Dr. Deaver's paper Dr. Delancey Rochester of Buffalo said that the most important thing with regard to appendiceal fistula is its prevention by early operation. This does away with all danger of complications and sequelæ. There is no medical treatment of appendicitis that is of any avail. Dr. Rochester used to consider that opium did good. He once reported five cases of appendicitis cured by means of opium. All five of these cases have since been operated on in recurrent attacks of appendicitis, and one of them has died as the result of complications due to adhesions that formed during the suppurative process in the region of the appendix. In a recent case under his care the parents refused operation when he advised it, and then he used the morphine treatment with some success. Later on the child developed appendicitis with some complicating peritonitis, and after the abscess was drained a fistula remained. This fistula did not develop for nearly three months after the original operation. When the appendiceal region was incised the appendix was found free in the abscess cavity and four perforations were found in it that showed how intense had been the inflammatory process.

Immediate Operation.—Dr. Rochester used to be an advocate of the morphine treatment for acute appendicitis in order to allow of interval operations. He does not any longer consider that this is good medical advice. As soon as the diagnosis is made surgical intervention should be advised. Only in cases where the family decline operation should the morphine treatment be applied.

Use of Morphine Stupid.—Dr. F. H. Wiggin of New York said that the stupid use of morphine in appendicitis cases should be stopped entirely. The morphine only serves to cover up the symptoms, and, if the patient is tided over an attack, the result is only the development of the complications from which fistulæ form when operation has finally to be done. Patients should be allowed to bear some pain, and when morphine is administered the family should be warned that, though the patient will be more comfortable, the condition is really more dangerous.

Opening of Abscess.—The mere opening of an abscess is not an operation for appendicitis and should not be so called. It is always unsurgical to open an appendiceal abscess and do nothing further. All diseased tissues should be removed in these cases, the abscess cavity freely flushed out with hydrozone and the general peritoneal cavity flushed with saline solution. Portions of necrotic tissue should be picked off with the fingers wherever possible. After thorough flushing there is no need of drainage. The abdominal cavity may be closed, just as if there had been no septic condition. It may sometimes be necessary to remove a few stitches, but this is a simple matter, and the direct closure of the abdomen will in most cases prevent the danger of subsequent hernia.

Large Abscesses.—Even if two or three pints of pus are taken from a large abscess it is not sufficient merely to drain it. The appendix should be carefully looked for and all remnants of it removed. Recently Dr. Wiggin was called to see a case of a very large abscess in a child in which so much pus was present that he feared there might be retention of urine, and he asked for the passage of a catheter before he was sure of his diagnosis. In this case during the operation Dr. Wiggin broke up all adhesions and found two other collections of pus, completely shut off from the largest abscess cavity. These would inevitably have been left and would have made the operation a failure if the usual timid method was followed. Besides these collections of pus, a large concretion was found. Dr. Wiggin did so much tearing of adhesions that the attending physician and the anesthetist feared for the result, but the child recovered completely.

Injections into Fistulæ.—Dr. Wiggin con-

siders it foolish as a rule to inject material into fistula for long periods. This is part of the old routine treatment that should be abandoned. As soon as the secretion ceases to be purulent and becomes merely mucus the outside of the fistula should be kept clean, the lower bowel should be kept empty and concentrated food should be given with the idea of making the feces solid. The fistula will heal better this way than by meddlesome interference with antiseptic washes.

Anomalous Cases.—Dr. Ferguson of Troy said that he had two recent cases of great interest because of the possibilities they provided with regard to subsequent fistulæ. In one case there had been trouble in the appendicular regions for several years. Finally an operation was undertaken and proved to be very intricate. The adhesions were broken up without serious injury to the bowel. No vestige of the appendix could be found though the site where it had been was still visible. After considerable search the naturally amputated organ was found three or four inches away from the bowel and fastened to the mesentery by adhesions. A fistulous tract connecting it with the colonic region was found and traced with a probe. Drainage was used in this case and later a hernia developed. This, however, has been cured by radical operation.

In a recent case Dr. Ferguson found a woman nearly moribund. He merely opened the abscess and she at once began to improve. A fistula remained, however, and it was concluded that the stump of the appendix was causing the trouble. At a second operation this was removed, but still the fistula did not close. A third operation had to be done in which over an inch of the distal part of the appendix was found buried in adhesions not far from the hepatic flexure of the colon and three or four inches away from the original site of the appendix. These difficult and trying cases show what constant surprises meet the surgeon in the abdominal cavity and also make clear that each case must be treated individually and not according to any cut and dried method.

Pre-Appendicitis Operations.—Dr. Richard Gibbons of Scranton said that operations for appendicitis should really not be necessary. The appendix should be removed before the diseased process had gone on to the stage of inflammation. A great change has come over medical opinion with regard to appendicitis in recent years, and we must go still farther. When the great eye surgeon Agnew died from appendicitis, although under the care of Sands and McBurney, the other great Agnew said to Dr. Gibbons, "The surgeon must wait in appendicitis for the formation of adhesions." This is just what surgical experience since then has taught us that we must not do. Just as in the question of suppuration in the middle ear, we do not wait for the development of mastoiditis, but incise the ear drum before it occurs, so, as soon as appendiceal colic occurs the appendix should be removed. The condition is easy to diagnose, and for its radical treatment it needs only a little knife and a needle and thread.

Immediate Operation.—Dr. Parker Syms of New York said that it is sometimes claimed that 80 per cent. of appendicitis cases recover without operations. This is, however, a very superficial view of the matter. Most of the recovered cases afterward have attacks which are either fatal or require difficult operations. Eighty per cent. is not encouraging in statistics of recovery since it means an awful mortality of 20 per cent.

Symposium on Malignant Growths.

Cancers and Infectious and Inflammatory Processes.—Dr. Albert E. Woehnert of Buffalo said that in many ways cancer cases resemble infectious and inflammatory processes. The kidney symptoms are distinctly similar. Dr. Osler pointed out that in 25 per cent. of cancer cases there are albumin and casts in the urine. In another 25 per cent. there is albumin alone. Only 50 per cent. are negative from the standpoint of kidney manifestations. Other observers have found a lessened amount of solids and uria in the urine. Still others have shown the presence of indican. These also are urinary manifestations of infectious disease.

Toxemia.—The toxemia present in cancer cases resembles that seen in infectious processes. This may of itself produce death. The coma that develops as the result of cancer toxemia is not unlike that of diabetes. The general condition in cancer cachexia resembles the prostration of a general infection. There is the fetid breath, the coated tongue, the anorexia, and the diarrhea.

Parasites in Cancer.—Dr. George Blumer of Albany reviewed this subject very thoroughly. He said that in most infections the proof of the contagious nature of the disease is either direct or indirect. Direct evidence is found by inoculation. Indirect evidence by infection of those who are collected together in certain neighborhoods. If distinct inoculation were possible we should expect to find many cases of association of cancer of the penis and cancer of the uterus. This does occur, but so rarely that it is evidently only a coincidence. Parts of tumors have been transplanted to other parts of patients' bodies, but very rarely. Some such inoculations, however, have been reported to be successful. Inoculation into other persons has been necessarily rare. In one experiment five persons were inoculated with cancer juice, but without success. The evidence in animals has confirmed the idea of the transmissibility of cancer. Cancroid of the vulva of white rats has been transferred by inoculation to the tunica vaginalis of other animals. Inoculability, however, does not prove infec-

tiousness, otherwise the transplantation of skin would seem to show infective power in skin-grafts. The evidence is not complete.

Recent Parasites.—In recent years the literature of the parasites in cancer has become enormous. Three forms particularly have been described, coccidia, yeast and rhizopods. The coccidial period received its principal confirmation from the coccidial tumors which occur in rabbits. Usually the parasites described have been intracellular bodies, sometimes containing a nucleus, at times striated, and these bodies push the nucleus of the cell aside. Some of the discoverers have described the multiplication of these so-called parasites by means of spores. Others have described sickle-shaped bodies. San Felice and Roncali thought that they discovered yeast-cells in cancer. As a matter of fact, however, anything round and apparently having a capsule has been considered by these observers as a blastomycyte.

Many of the appearances found in cancer cells and thought to be parasites can be explained as areas of degeneration within the cell or as leucocytes that have wandered into the cell, or as manifestations of endogenous cell-formation. Recently Borell has shown that practically all the appearances that were supposed to show the presence of parasites can be explained as abnormal conditions of the centrosome in the new formation of cells in cancer-cells. This seems to furnish a complete explanation of many mysterious experiences and Borell's illustrations show how well and how carefully the work has been done. Leyden recently described an ameba found in the ascitic fluid of an abdomen in which cancer of the omentum existed. This could not be connected, however, directly with the cancer. All recent work points to the fact that any organism that may exist in cancer does not grow on any ordinary culture medium. Organisms that have been found were really due to chance contamination. Certain evidence collected of late rehabilitates some of the old arguments with regard to the possible infectious nature of cancer. A German observer showed recently that in a town of 3,000 inhabitants cancer occurred only in definite locations. There were two suburbs to the town, an eastern and a western. No cancer cases occurred in the western suburb; practically all the cancer cases occurred in the eastern suburb, a few being in the eastern end of the town proper. All the cases occurred in houses situated on a sort of creek or ditch. In this ditch the inhabitants had the habit of washing the vegetables that they consumed. Most of the cases of cancer occurred in the liver and stomach.

Buffalo Evidence.—A careful inspection of the mortality statistics shows that in Buffalo, where cancer is especially frequent, certain wards have many more cases of cancer than others. These wards are principally inhabited by Germans and Poles, who suffer five times as frequently from malignant disease as the inhabitants of other parts of the city. Among these people cancer of the stomach occurs ten times more frequently than is the average in the rest of the population. It would seem then that something in their diet favors the development of cancer. These statistics would lead one to suspect parasitic nature of cancer. The material is, however, too small for a definite conclusion in the matter. A careful collection of clinical material in this matter will undoubtedly bring us precious information and the collection of such clinical material only requires the co-operation of intelligent physicians throughout the country to make it of immense value.

Intrathoracic Growths. — Dr. Alexander Lambert of New York said that these are nearly always malignant. A few dermoid cysts, fibromata and echinococcus cysts occur. In the pleura malignant neoplasms are usually secondary to growths elsewhere and the existence of a cancer focus elsewhere is the best diagnostic element in a doubtful case of obscure intrathoracic symptoms pointing to pleural involvement. They cause either effusion or a dry pleurisy. In cancer cases the pleuritic exudate is hemorrhagic. The differential diagnosis from tuberculosis is not easy. The absence of tubercle bacilli or of characteristic tuberculous cells or the presence of cancer-cells may help to the decision. In the lung, primary cancer predominates over secondary growths. Carcinoma is seven times more frequent than sarcoma. It occurs by preference on the right and in the upper lobe. It may be nodular in form and spread over the lung so as to simulate miliary tuberculosis. Cancer of the lung may cause swelling of one side of the thorax.

Lung Cancer Symptoms.—The symptoms are increasing dyspnea and pain for which the ordinary pulmonary condition can be found. There is apt to be a characteristic sputum. This is called raspberry or currant juice sputum from its color and general appearance. The diagnosis in cases of diffuse cancer of the lung is not easy. The differential signs from tuberculosis are the less amount of expectoration and the lower febrile course of the temperature.

Mediastinal Growths.—These used to be thought mainly cancerous in character. Recent statistics, however, show that sarcomata occur more frequently. There usually are signs of vascular compression with these growths, and sometimes of nervous irritation or paralysis from pressure. Irritation of the recurrent laryngeal nerve may cause a brassy cough and other symptoms simulating aneurism. Percussion usually shows a dulness under the sternum and extending on both sides of the sternum, but asymetrically. There is often a paroxysmal cough not unlike whoop-

ing-cough. This is almost pathognomonic of mediastinal tumor. At times the tumor grows very large and produces diffuse dulness to percussion. These large tumors are usually lymphosarcomatous in character. As a rule the limits of the tumor can be readily mapped out by percussion, because the lung resonance helps the diagnosis. The boundary of the percussion dulness is often a sinuous line.

Cancer Statistics.—Dr. James Ewing, of New York, called attention to the great discrepancies in the statistics of the results of operations for cancer in the hands of various operators. To take only the one form of cancer of the breast, within the last year or two one surgeon has been reported to have had as high as forty per cent. of recoveries without recurrences for over three years. These were set down as radical cures. A careful operator here in New York at a large hospital says that not more than three per cent. to 5 per cent. of his patients fail to have recurrences. Needless to say the greatest care is taken to make the operation include as far as possible all infected tissue. A prominent surgeon says that he has never had a cancer of the uterus that failed to return. In 80 cases of carcinoma of the larynx operated upon, all but one had recurrences. The question then arises, Is there really such a thing as radical operation for cancer?

Pathological Considerations.—So far cancer operation statistics have been made practically entirely without the co-operation of the pathologist. Certain terms as alveolar or adenocarcinoma have been employed in describing these tumors, but their meaning has been very loosely applied. We are coming to the realization now that the histological structure of the malignant neoplasm rather than any special technic or completeness of the operation is the important factor in the prognosis of operated cancer cases. Certain well-recognized forms of cancer are almost sure to return no matter what the extent of the operation. Others show very little tendency to recur even when the operation seems conspicuously incomplete and even to invite recurrence.

Mammary Cancer Classification.—Cancer springs from many tissues in the breast, from the skin, the alveoli, the lacteal ducts, the endothelium, etc. An attempt at the classification of the malignant tumors of various origin according to their malignancy seems desirable. Those that have their origin in the skin of the breast are distinctly less malignant than any other cancers of the mammary gland. The most common form of this type of cancer is the simple epithelioma. Involvement of lymph-glands takes place very late in the disease and not until ulceration has taken place with consequent provision of the opportunity for the epithelial cells to reach the lymph-ducts. At times there is an anaplasia of the epithelial cells and more rapid invasion of the lymph-glands, but even these forms of cancer are not difficult to cure completely and radically. The danger of recurrence if all apparently infected tissue is removed is very little.

Paget's Disease.—This form of malignant disease of the breast is really cutaneous epithelioma. It is essentially skin cancer, and though in the course of time it may invade the lacteal ducts it should never be difficult to cure. If the affected tissue is all removed it should not recur. Dr. Ewing has seen recently a specimen from an operated case of Paget's disease in which the incision had been made through the affected tissues. Needless to say there was under the circumstances inevitably immediate recurrence in the scar of the operation wound. Such cases are not rare for the Paget's disease often extends beyond the apparent tumor in the breast, and at times beyond even the suspicious appearances on the external skin.

Clinical Course of Carcinomata.—The age and the rapidity of growth of a given tumor provide the best elements for its prognosis. It is much more important for the surgeon to state in making his report of the case that the tumor has been of slow or rapid growth before operation than to tell its size and the amount of involvement of gland that it had caused. As a rule the so-called reticular carcinomata are not very malignant, do not grow very rapidly and show no very marked tendency to recurrence.

Adeno-Carcinomata.—These forms of malignant tumor are always limited in their invasion and their removal is, as a rule, followed by true radical cure. It is not unusual for the surgeon to remove a so-called adenoma and for the pathologist to find there scattered islets of carcinomatous tissue. This is then added to the list of cancers removed by the surgeon and without due reason goes to swell the number of cured cases. Adenocarcinoma is not infrequent during the milk-giving period and while it often causes considerable annoyance to the patient it is usually not malignant and does not recur. The good rule to remove all tumors that occur in the breast leads to its removal. It sometimes does degenerate malignantly, and so its removal is advisable.

Pure Carcinomata.—These malignant tumors come from two sources, the true milk-secreting cells, or the lining cells of the ducts. When composed of the lining cells of the ducts, these carcinomata often retain a certain amount of at least simulated tubular structure. The cells arrange themselves in cylindrical groups, as if they still lined conducting tubes. This is one of the most diffuse form of cancer and is very malignant. It can be recognized even in atypical specimens, because it presents no evidence of milk-making. Occasionally the presence of the cancerous nodules irritates the secreting cells of the breast, and so there are some scattered manifestations of colostrum. These are, however, not typical enough to make us think that the gland-cells themselves are involved.

True Alveolar Cancer.—These malignant tumors come from the true secreting cells. The tumors abound in colostrum corpuscles and their evidence is of value as showing the fundamental

cells of the new growth. This form of cancer is also extremely malignant. The nests of cancer-cells grow with more or less of lumen, and in the spaces thus formed colostrum is found. Of the two forms of true cancer, the alveolar and the duct carcinomata, the greater malignancy belongs, perhaps, to the latter.

Insidious Carcinomata.—Malignant tumors which spring from the lining cells of the lacteal ducts are often most insidious in their course. They often do not produce a definite tumor and they may not grow rapidly. The lymph-glands will often be tightly distended with metastatic cancer-cells, before the tumor in the breast has given any serious evidence of its presence by pain or discomfort, or even been called to the patient's attention by the presence of a hard portion in the organ. There is often a capsule present and this protects the skin from invasion, but does not prohibit the entrance of cancer elements into the lymphatics.

Malignancy and Prognosis.—True carcinomata are most malignant when they occur during the period of lactation. When the essential elements of the gland take on a neoplastic process during the active period of function, they are especially liable to obtain abundant nourishment and consequently to grow very rapidly. Such tumors particularly are apt to be followed by recurrences, and it is by these that surgical cancer statistics are spoiled. It is only, however, when the surgeon gives the details of the age of the patient, the clinical course of the tumor and the morphology of the histological elements that compose it, that his statistics are of true service in judging of the results obtained by surgical intervention. There is in this matter an important field for clinical observers and for the collection of clinical material that will be of great benefit to our knowledge of cancer and its curability.

Caustics in Cancer.—Dr. A. R. Robinson of New York spoke of the use of caustics in the treatment of carcinomatous growths. They are especially useful in the treatment of carcinomata of the skin. Epitheliomata are divided into three forms. The superficial, or discoid, the deep, and the papillomatous. As a matter of fact, however, there is no hard and fast line between these forms. It must be borne in mind that the apparent limit of a skin cancer is never its true end. Always beyond the periphery of the apparent tumor there are cancer-cells in the tissue that must be destroyed when any effort at removal is made or the cancer will surely recur. As a matter of fact, any interference with a malignant tumor that does not destroy all the cancer-cells in the vicinity is apt to produce hyperemia and an inflammatory reaction with lowered resistive vitality of the normal tissues, which thus puts the cancer-cells in the best condition for growing rapidly. This makes the prognosis worse than before.

Forms of Caustics.—It is evident that the ideal in the treatment of cancer is the removal of all the malignant elements. This can be accomplished either by the knife or by any other destructive process. Cancer never diffuses itself regularly. On one or more sides of the tumor there may be little or no extension, while on the other side, the growth may extend widely beyond the apparent limits. In order to remove with the knife, therefore, the cut must be made deeply into healthy tissue . On the face, this is productive of very serious deformity. Caustics, therefore, can be used to destroy just sufficient tissue, the operation being watched very carefully and thus there is less disfigurement. Zinc chloride has been used for this purpose, and when combined with cocaine may be employed without pain, but it has no advantage over the knife, since it produces too much loss of tissue. Caustic potash may be employed with very good effect. After its application the slough is removed and another application of the caustic made. After its employment there is an intense inflammatory edematous condition in the tissues surrounding the tumor. In this zone of inflammatory disturbance the circulation is retarded, certain tox-albumins develop as the result of the lowered vitality in the part and these tend to destroy cancer-cells that may be present even at a distance from the malignant growth itself. In certain respects this form of treatment is ideal, and can almost be said to be selective in action, destroying the neoplastic cells much more than the true tissue cells of the part. A still better caustic, however—because of its well-marked tendency to selective action—is arsenious acid. It does not seem to act as a chemical, but as a devitalizing agent and picks out particularly the neoplastic cells, for its work of devitalization. Dr. Robinson does not think that more than one in twenty of the epitheliomata of the face need to be treated with the knife. Arsenious acid removes the tumors quite as completely and effectually and with much less subsequent disfigurement. The chances of recurrence are great reduced, for there is always hesitation with the use of the knife in going sufficiently wide of the apparently abnormal tissue to remove outlying cancer-cells.

Roentgen Rays.—Dr. Malcolm Morris, of London, the distinguished dermatologist, when on a visit to this country a few weeks ago, said to Dr. Robinson that for deep tumors of the upper part of the face the Roentgen rays are an effective remedy. Dr. Morris is a thoroughly conservative observer, and so it would seem that for the hopeless malignant tumors, beyond our skill heretofore, this new remedy provides a very promising method of treatment.

SOME OBSERVATIONS ON SOUTHERN CALIFORNIA.[1]

BY SAMUEL A. FISKE, A.M., M.D.,
OF DENVER, COLORADO.

THE State of California, the second in size in the United States, covering 155,980 square miles of territory, is usually subdivided, for convenience sake, into Northern, Central and Southern California, each portion having its well-defined characteristics not to be confounded with those of the others any more than one brother should be taken for another, simply because he bears the family name. In Southern California I spent the months of February, March and April of this year and it is of this portion that I want to say a few words, in a chatty way.

By Southern California is meant that portion of the State which lies to the south of Tehachapi Peak, or, roughly speaking, the seven southern counties of Santa Barbara, Ventura, Los Angeles, Orange, San Diego, Riverside and San Bernardino. On the Atlantic Coast this would reach from a point somewhat south of Cape Hatteras nearly to Charleston. Its boundaries, for vacation purposes, are fairly represented by Santa Barbara to the north, San Diego to the south, Redlands to the east and Catalina Island to the west. Parallel with the coast, but back from it at varying distances up to ninety miles or so, is the Coast Range which cuts the sea-coast off from the desert to the east, and at right angles with this range, and running sometimes to the very shore, are numberless spurs, making a series of valleys, but sparsely inhabited.

While there are characteristics which these places have in common and which are not to be confounded with those of portions of the State further north, they nevertheless differ from each other; for in this region we have seashore and mountain, low and high altitude, the ocean fog and the absence of that fog; so that these conditions must constantly be borne in mind. Here are the well-known places of San Diego, Coronado, Lakeside, Santa Anna, Orange, Los Angeles, Santa Catalina Island, Santa Barbara, Montecito, the Ojai Valley, Nordhoff, Pasadena, San Bernardino, Redlands, Riverside, Mentone, Colton, Strawberry Valley, etc., while Monterey, Santa Cruz, San Jose, and San Francisco lie farther to the north and are in Central and not Southern California.

It so happened that our journey was made in a snow-storm, and icicles hung to the car windows; this emphasized to us the fact that from first to last we did not see snow in Southern California, except occasionally on the distant mountain peaks. The ice on the tables was manufactured and most of the houses are supplied with "cool rooms," rather than refrigerators. On the other hand, but little provision is made for fires. The hotels have steam heat here and there, to take the chill off of the air when necessary, but coal is brought from a distance at a considerable cost, and a few sticks of cottonwood are harbored almost as an easterner would cherish hickory. At times a blazing hearth is cheering, and is welcomed when met.

The foliage, too, struck me as being different from that to which we are accustomed. It was the winter season and the green trees were of the evergreen variety—cypress, palm, pepper, eucalyptus, rarely a pine; live oak, magnolia, orange, lemon and olive there were of course, and groves of these trees are on all sides in this southern country. I saw none of these as we went further north. The elms, maples, oaks, chestnuts and spruce were absent, though I did run across some beeches high up in the cañons, and now and then I saw a drooping willow. The mistletoe in large clusters, generally on sycamore trees, was not an unusual sight.

The bird-life was novel and interesting. The mocking-bird, singing away from some thick tree or chimney-top, the wild canary, the linnet, the quail and, most of all, the meadow-lark, made music. It seemed odd to have the lark pouring forth his melodious strains from the top of a post on the one side, while the surf was breaking on the beach on which we were walking and the snipe were scurrying before the incoming wave, and all this in early February, when we could see snow on the distant mountains.

And who can speak of this country and neglect to mention the flowers? One thinks of roses blooming on all sides in the open air in midwinter in California, but he will not soon forget the luxuriant growth of the gold of ophir roses, trailing over the very roofs of the cottages, or, with their companion, the cherokee, making an impenetrable hedge for hundreds of feet; nor the paths bordered by marguerites and calla lilies. And as for the orange groves, with their trees weighted down with fruit and at the same time white with blossoms, and the air heavy with fragrance, the experience is a never-to-be-forgotten one. As one invariably associates some particular brookside with the trout, or Duluth with the planked whitefish, or lower Cape Cod with the broiled bluefish steak, or Digby, Nova Scotia, with fried herring, and each particular food never tastes so good anywhere else, so one can never, I think, wander amongst a grove of orange trees and pick up from under one of them a Wash-

[1] Read at the meeting of the American Climatological Association, 1901.

ington navel that has just fallen, so ripe that it is thrown down by the wind, as juicy as any watermelon, dripping as it is peeled by the fingers (without a knife) and as sweet as sugar—one cannot have such an experience, I think, and not put a pin in it to fasten it there and make it one of the events of one's life. One may eat the best oranges the market can produce, surrounded by all the comforts and luxuries of club life, spotless table-linen, delicate china, polished silver, steel and glass, noiseless carpets, and attentive servants, but he will still sigh for the hillside, the view, the carolling of birds, the breeze, the perfume, the sunshine, the luscious and juicy fruit and that orange grove.

This country is full of seeming contradictions, and by the side of this cultivation may be rough fields or tall growths of cacti or what looks like waste land, acres upon acres of waving grain, bordered by barren fields, or even by marshy lagoons. Like a pretty girl, she pouts and smiles with the same lips, but she is always beautiful. There are the same reds and browns as in the landscape of Colorado, but it is not so rugged and the effects of rocks and boulders is lacking. In fact, were a comparison to be made between two things so alike in some respects and unlike in others, it might be said that Colorado is stimulating, while California (*i. e.*, the southern portion) is soothing. The soil is porous and dries rapidly, and dust is on the clothes and shoes and follows the carriage wheels.

The towns are furnished with abundant water supplies of clear mountain water, and the lay of the land makes fine drainage, which in many instances is into the ocean. While dryness is the prevailing impression, I recall a wet and nasty day spent in Los Angeles, in the very first of February. I think of down-pourings of rain and puddles at Coronado at the same time, of washouts and delayed trains, etc., but I also think that when the clouds did roll by, and the sun did come out, which was about the middle of the month, it came out to stay, and I cannot recall having had to use my umbrella in Southern California after that.

This leads one to speak of the rainy season for which California is famous and which, to quote from a writer on Southern California, "usually begins in November, though slight showers may have occurred in October, and it lasts until about the middle of April."[1] From the same writer, a former member of this Association, William A. Edwards, M.D., in "Two Health Seekers in Southern California," we learn that an average of twenty-four years puts the total annual rainfall at 10.23 inches, of which 8.75 inches fell in the four months of December, January, February and March. But then there are the fogs, which come rolling in from the sea in great banks, and may totally obscure the sun until late in the day. Sometimes they obscure it all day long. I have frequently seen the trees drip, drip, drip, as though from a shower, and all from a fog or a heavy dew. In the morning the asphalt on the streets is often black as though from a rain, but really due to fog or dew; and the moon may shine clearly and the pillars of the veranda be wet from the same cause. One needs wraps at night, and sitting out of doors is almost out of the question. I am speaking now of the seashore and of the winter and spring months.

A comparison shows that this climate, which is a dry seashore climate, has a high relative humidity as compared with that of Colorado, and that its absolute humidity is, in the winter and spring months, about two and one-half times as great. This is worthy of consideration, especially in relation to pulmonary disease, and personally I should expect better results in persons in the early stage of this trouble, and of recuperative power, in the drier mountainous regions than at the sea level of Southern California, even if the climate is less rigorous than that of most places along the Atlantic seaboard, or vastly drier than Florida and around the Gulf.

It has been well said, with reference to quite another subject, "They reckon ill who leave me out," and so the man who leaves out of the consideration of this climate its fogs, which do exist, which are cold and nasty and depressing to mind and body alike, does not reckon aright. While this is preëminently a region of sunshine, one may lose the feeling of buoyancy and exhilaration experienced in the Rocky Mountains, especially in the early morning, caused by a clear sun, a blue sky and warm air—all because of the fog.

But equability is the keynote to the climate of Southern California. The writer above quoted, says: "There is little seasonable change in the extreme southern part of the State. . . . We do have cold days. We also have those that are altogether too warm for pleasure and comfort. But we almost never have sufficient cold to injure or kill the most delicate vegetation, nor, on the other hand, is the heat ever prostrating or dangerous to the individual or his animals."

For my own part, I was wont to walk in a golf suit, and frequently the perspiration would stream off of me in drops, as on the Maine coast in summer, and I would see shirtwaists and fur boas, straw hats and Derbys in the same crowd. The Marine Band from the U. S. S. "Iowa" would give open-air concerts in February, and the crowd of several hundreds would sit or stand around or even lie on the grass, in perfect comfort, and listen to the music for an hour and a half, from three to four-thirty in the afternoon. Notwithstanding this, it was advisable to have an overcoat at hand and to be in the house in the evening. This was at sea-level. I found the mountain region somewhat drier, but there, too, the same rule held, though not so forcibly.

The daily motion of wind is slight and at the seashore did not interfere with plans. Higher up in the mountains, I experienced several dust storms that would have done credit to a region

[1] In February of this year the rainfall was 4.77 in. as against an average of 2.05 in., while the four or five seasons preceding were so dry as almost to dry up the orange crops, and in March there were only two cloudy days.

severely criticised on their account; and a housekeeper at Redlands complained of the difficulty of keeping the house clean.

To sum up, my strongest impression is of sunshine, a dry soil and mild temperatures. I found this a land of contrasts, novel and interesting, but of contrasts just the same. Orange blossoms and ripe fruit on the same tree. The place, the country, and the atmosphere were pacific and soothing; some found them enervating. People from Colorado came to California for relaxation, while, on the other hand, some went from California to Colorado for invigoration. Equally with the surrounding atmosphere, the social tone would vary from the crowd on pleasure bent to one of simplicity and refined retirement. One lived in flannels all day long, and fished, hunted, rode horseback or played golf, or he sat listlessly around and gaped at the crowd, composed of statesmen, diplomats, admirals, generals, handsomely dressed women, wealthy men—just as the spirit moved. One man remarked: "I thought we had to go to the Riviera to find this."

There seem to be two distinct seasons in the hotel-life of California. In the winter comes the tourist from the East; in the summer, the migration of the Californian himself; and I am very generally told that the summer is the choice season.

The distance intervening between the Atlantic and the Pacific Oceans seems appalling to many. But some of our best railroads run into Chicago and from that place to Los Angeles is less than three days of travel, which may be spent in a sumptuously appointed train that, in elegance and comfort, will bear a favorable comparison with those farther east.

EXAMINATION OF THE MOUTH IN INFANCY CHILDHOOD.

BY JACOB SOBEL, M.D.,

OF NEW YORK;

ACTING VISITING PHYSICIAN (DISEASES OF CHILDREN) AT THE GOOD SAMARITAN DISPENSARY.

THE more one examines infants and children, the more deeply does he become impressed with the importance of a thorough and systematic inspection of the mouths of these little patients. To those mainly accustomed to adult oroscopy, it may seem that this examination is a very simple procedure and that a superficial look, as it were, is all that is required. Such is not the case, however, as those identified with pediatrics can testify.

In the first place, examination must be conducted not only without the aid of the patient, but in most instances much against their will and inclination; and, secondly, the mouths of infants and young children present a picture so different from that of the adult that many normal or harmless features will appear as pathological lesions to one not familiar with their examination. For example, not only are the lateral surfaces of the hard palate very much paler in infancy, but in many instances the lips appear to be composed of two parts separated by a sharp line of demarcation, that is, an inner or bluish and an outer or reddish part. I have had both of these normal conditions referred to me for question as to their specific character.

Again, congenital peculiarities of a perfectly harmless nature may cause unnecessary alarm and interference, for instance, the case in Prof. Filatow's family,[1] in which a congenital, irregular grayish patch on the fauces was diagnosticated as diphtheria. In several instances, I have observed enlarged follicles of a congenital nature on the tonsils, which might have been mistaken for membranous deposits.

For a thorough inspection of the mouth in infants and children three conditions are absolutely necessary, namely, good position, good light, and a good tongue depressor.

A great deal of unnecessary exertion on the part of the patient, mother, and physician, is often wasted in attempts to "hold the child down" in unnatural positions. Not only do these render examination difficult and imperfect, but they endanger the mouth by forcible examination, which, as Jacobi has pointed out, is above all to be avoided in diphtheria; in this condition alarming collapse and even death having followed such manipulation.

The ideal position is to have the back of the child rest against the mother's right breast, its head against her shoulder, her left hand holding the child's knees, her right its hands. The left index finger and thumb of the physician are placed on the infant's temporal region and with the palm the head is held firmly against the mother's shoulder. It is surprising to see how rarely such a simple procedure is adopted and how frequently physicians will resort to all kinds of positions for examination.

Without good light nothing can be accomplished. Direct daylight thrown into the mouth answers every purpose; shadows are to be avoided, hence daylight from one direction must be used. In dispensary practice I have often found subdued light more satisfactory than bright sunlight. In exceptional instances a forehead reflector with daylight or artificial light may be necessary; the latter is preferable because not so diffuse, even though the former retains the natural color of the parts more clearly. The forehead reflector is far superior in my opinion to the hand mirror, since it fulfills every indication of the latter and at the same time leaves the hands free for operative or medicinal intervention.

At night it is always wise to examine with a forehead reflector or an especially constructed pocket electric lamp. Unfortunately the lamp requires constant care, for the cells need frequent replenishing and the light is often out of order when required most. For that reason I prefer the forehead reflector with candle or gaslight, or, if possible, the Welsbach.

The third requisite is an efficient tongue depressor. What constitutes a good tongue de-

[1] C. Herrman, N. Y. Medical Journal, Jan. 10, 1901.

pressor will depend greatly upon the personal equation. In private practice, conditions vary from dispensary work and hence must be considered separately. Broadly speaking, tongue spatulæ may be grouped into those with and those without a handle. Among the latter the ordinary tea- and tablespoon or the wooden slips, as used by the New York Board of Health, are the most convenient. The great advantage of these is that they are used for one patient only and then immediately boiled or burned. These advantages are more than counterbalanced, it seems to me, by their lack of firmness and the impossibility in numerous cases of obtaining a proper *point d'appui;* the wooden spatulæ, being of various sizes, are uncertain and the spoon does not always admit of firm pressure, for the resistance which some infants offer to the depression of their tongues can only be appreciated by those who have experienced it.

I have used the spatula with a handle in dispensary practice and have found it most serviceable. Chapin's tongue depressor has served me well, particularly when I desired a very thorough inspection of the pharynx and tonsils; in fact, with it, inspection of the anterior surface of the epiglottis is frequently a simple matter, especially in very young children. Like all other tongue depressors, however, it has failed me when I desired a thorough examination of the under surface of the tongue and floor of the mouth, and particularly in "nicking" instances of tongue tie. True, the wide end of a grooved director would apply, but it occurred to me that a combination of depressor and director, so to speak, would answer every purpose, especially where some sixty to one hundred or more children were examined daily. Accordingly, Messrs. Tiemann & Co. have perfected for me an instrument which I have used, mostly in dispensary work, with great satisfaction and which I present for consideration and trial.

It consists (see Fig.) of two blades connected by a hinge joint which permits of its being folded. The smaller blade measures 3½ inches in length and ½ inch in width at its broadest part; the larger blade measures 3⅞ inches in length and ⅞ inch at its broadest part. The depressor is made of nickel plated steel, is highly polished, easily manipulated, light in weight and portable.

It combines the advantages of a tongue depressor and the broad end of a grooved director and is designed mainly for the examination of the mouth in infancy and childhood. It is modeled in part after the Chapin instrument in that the end is somewhat dipped in order to pull the tongue downward and forward; it is notched in order to grasp the frenum and admit of a thorough inspection of the sublingual region and floor of the mouth, as well as for "nicking" the frenum in tongue tie. Many lesions otherwise overlooked—sublingual ulcers, aphthæ, dilatation of the sublingual veins, small nævi, cysts, adherent frenum, etc.—are recognized with the aid of this instrument. Any frenum is brought within its grasp, the longer and thinner ones far more readily than the shorter and thicker ones. The smooth edges prevent any discomfort or injury and the end is sufficiently thin and narrow to be passed along the lower alveolar border to the pharynx—an important requisite in obstreperous children. The larger end may be found efficacious in cases of so-called uncontrollable tongue in later childhood or the adult.

No oroscopic examination to my mind is complete without a thorough inspection of the under surface of the tongue and floor of the mouth, and for this purpose an instrument after the above fashion has been found necessary in my experience.

When cutting the frenum the depressor may be held in the usual manner, or reversed with the concavity of the blade pointing toward the face.

In using the instrument, one should insert it below the tongue in the median line, when in most cases the frenum will fall within the notch; if not, a little gentle manipulation will effect the desired result. In examining the tonsils and pharynx, if

the instrument is passed far back on the tongue, the epiglottis in the vast majority of cases and the upper part of the larynx in favorable ones will be brought into view.

I am not unmindful of the fact that a criticism as to the difficulty of proper cleanliness might be raised against it, as against all other metallic instruments; in my dispensary work, however, three instruments are at my disposal; these are kept in Thiersch's solution (double strength) flavored with a few drops of the oil of anise. When the depressor is used in diphtheria, scarlet fever, whooping-cough, measles or in suspicious cases, it is immediately sterilized. In private practice sterilization by boiling is but a question of a few minutes and is readily carried out.

Position, light, and depressor being ready, examination is begun. If the child cries and opens its mouth so much the better, for the instrument is inserted at once and the cavity inspected. If difficulty is encountered in opening the mouth, the spatula is passed at the side along the lower alveolar border to the pharynx; once this is irritated the mouth will open. On account of this difficulty the depressor must not be too wide or

too thick and yet not too thin or sharp as to cause injury. It has never been found necessary to resort to closure of the nostrils, nor have we met with any child so uncontrollable as to deter examination.

It has been my experience that many physicians, certainly beginners, when examining the mouth, see nothing but the tonsils and pharynx. It seems as if these constitute for them the entire oral cavity.

A systematic examination of the mouth must be conducted to my mind as follows: The depressor is inserted at the left angle of the mouth, the cheek and lips everted, then at the right angle, and the cheek and lips everted. The spatula then catches the frenum and the under surface of the tongue, the frenum and the floor of the mouth are observed; the spatula being removed the upper surface of the tongue is viewed; the latter is then firmly depressed and the hard and soft palates, fauces, tonsils, pharynx, and in the vast majority of cases the epiglottis are observed.

A complete inspection, then, embraces four views, namely, (1) cheeks, lips and gums, (2) under surface of the tongue and floor of the mouth, (3) upper surface of the tongue, (4) hard and soft palates, fauces, tonsils, pharynx and epiglottis. The first step—eversion of the cheeks and lips—being the least disagreeable, gains the confidence of the patient for the more uncomfortable examination of the tonsils and pharynx.

The very first step may give us information as to the presence of catarrhal, aphthous, parasitic, ulcerative, or gangrenous stomatitis; epithelial pearls, Koplik's spots, dental ulcers, progress of dentition, character of the teeth and gums (spongy or hemorrhagic), purpuric spots, molluscum epitheliale, verrucæ, anemia, cyanosis, swelling of the outlet of Steno's duct, etc.; the second step tells us of the condition of the frenum (long, short, thick, adherent or vascular), the presence of sublingual ulcers (pertussis), the condition of the sublingeal veins (dilated in sporadic cretinism), patches of stomatitis, and the general appearance of the floor of the mouth. The third step will give us information as to the color, size, and general appearance of the tongue, whether coated, clear, anemic, congested, hypertrophied, strawberry, fissured, or presenting irregular exfoliated areas (so-called ringworm of the tongue), and the final step may show us perforation, deformities, or congenital defects of the hard palate, stomatitis, purpuric spots, lesions of varicella and variola, papular eruption of measles, Epstein's pearls, Bednar's aphthæ, an elongated, short, bifid or edematous uvula, jaundice, faucitis, hypertrophied tonsils, pharyngeal inflammation, exudate or growths, retropharyngeal edema, adenitis or abscess, pharyngeal granulations (important in the diagnosis of adenoid vegetations), tonsillar inflammation or exudates, peritonsillar abscess or edema, etc.

When one is brought face to face with great numbers of children, one soon finds the need of rapid and yet thorough examination. No thorough examination can be conducted rapidly unless it be systematized. The aforesaid method has been used by me for some time and I have by this means not only been enabled to make this important examination with thorough satisfaction, but I have observed a very large variety of conditions.

At the Good Samaritan Dispensary every mouth is subjected to thorough and systematic examination, irrespective of the ailment, and it is only by methodical means that we are enabled to control a large material with justice to the patient and satisfaction to ourselves.

Unless the tongue be firmly depressed so that the tonsils roll out, many patches and ulcerations, diphtheritic and otherwise, which are situated at the lower and posterior part of the tonsil will be overlooked. This often causes the patient to gag and cough, so that it is well for the physician to protect his eyes with a pair of ordinary glasses, in cases known to be contagious or in suspected ones.

Whatever be the tongue depressor employed, let system govern the examination of the mouth, and let every portion of it be thoroughly inspected lest gross errors be committed.

1828 Madison Avenue.

A CASE OF CONCUSSION OF THE BRAIN AND HYSTERO-EPILEPSY.[1]

BY WILLIAM B. NOYES, M.D.,
OF NEW YORK;
ATTENDING NEUROLOGIST TO THE DEMILT DISPENSARY.

THE following case has been fought out on its merits in lawyers' offices and in the courts. Those who have studied it and expressed the usual positive opinions of "medico-legal experts" are probably all agreed that several interpretations might be put upon it, varying not a little possibly from their opinions as stated on the witness stand.

The patient was a man, George A., aged thirty-five years, married. Three years ago, when employed in his occupation as a telegraph lineman, he climbed a rotten telegraph pole and fell from the height of 15 feet, striking his head. He was stunned and his scalp was severely cut. He was taken to the Staten Island Hospital and was able to go to his home in Brooklyn the next day. Of the events immediately following the accident he has had no recollection since. Epileptic fits occurred when he reached home and recurred frequently afterward. The diagnosis made a month later at Bellevue Hospital was concussion of the brain and traumatic epilepsy. To relieve his condition the operation of trephining was strongly urged and refused by the family. He was considered seriously injured. There is record of decided change in his mental condition, his wife stating that he became morose and quarrelsome.

Previous history proves that he has always been able for years to do lineman's work and had never had a fit. There was no history of alcoholic excess.

[1] Read before the Medical Association of the Greater City of New York.

He had been involved in some trouble with the police two years before his accident on account of having in his possession some wire that did not belong to him. On account of this he had served a short term at Sing-Sing.

The card of physical examination by the Bertillon system taken at that time showed that his physical development was normal, no marks on head or body. Eyesight normal, although the photograph recorded a slight squint. There is no record of any fit at Sing-Sing, although a fainting fit of some sort was claimed to have occurred at the White Plains jail before he went to Sing-Sing. This was seen by one person only.

I saw him first March 13, 1900, at his home. He was having a fit at the time. He was unconscious, breathing heavily, lying prone in bed, more or less rigid, the face red. The clonic convulsions had ceased. The eyelids opened easily, pupils not especially dilated. Mentally, he was at first unconscious; after 15 minutes, partially conscious, though confused. After his mind had become clearer, he seemed to be much fatigued mentally and physically and impatient of questions. His memory was poor. He told of his accident and subsequent illness, but was not clear in his mind as to what had happened after his fall. The fit seemed to me at the time to be a typical epileptic convulsion, but a second fit resembling the first was precipitated by pressing on a spot on the left side of his head. He could not see distinctly with his right eye, not distinguishing fingers five feet away. He complained of seeing everything red before his right eye before the fit comes on, and at the time I saw him. The motor nerves of the eye and other cranial nerves were normal. Speech was normal, after the fit was over. His extremities showed a *left* hemiplegia, during and for a while after the fit. Rigidity was not marked. There was no tremor. Knee-jerks were absent at the time. Sensation to touch and pain deficient over the entire left side, especially over upper arm and above middle of the leg. Hyperesthesia over right breast. Intense hyperesthesia over area on the left side of the head, 1½ inches above the posterior corner of the eye, near junction of temporal and parietal bone. Pressure over this spot at the close of the fit produced a new convulsion. He complained of intense pain in that region at that time and at other times, especially before a fit.

A second examination at my office gave the following data. He appeared to be a strong, healthy man, weighing about 150 lbs. and height 5 feet 8 inches; grip on dynamometer on both sides 35 pounds. There was no ataxia; the knee-jerks were present, and alike on both sides. There was also noted unsteadiness and a coarse tremor of the hands. Examination of the eyes by myself and later by Dr. Curtis Carter showed that he was suffering from an extreme concentric limitation of the visual field of both eyes. A plain glass gave him normal vision, thus establishing a diagnosis of hysterical amblyopia. Ophthalmoscopic examination was negative and refraction normal. Left arm weak and partially anesthetic. Left leg weak. Left side of his head tender over a depression existing near the junction of the frontal, parietal and temporal bone located 9 cm. from alæ nasæ; 15 cm. from occipital protuberance; 8 cm. from ear; 7 cm. from frontal bone. Slight thermalgesia. No hyperesthesia. During the year following the accident he had had occasional fits seen by various witnesses, the convulsions appearing to be of the nature of epileptic fits.

He tried to get work, but was unable to do anything continuously from his shattered physical condition. Mentally he changed much, being morose and at times acting as if insane. He suspected his wife, and left home for some months, living under an assumed name. This mental condition had improved at the time of my second examination and at the time of his trial he made a favorable impression on the spectators.

Traumatic cases of this sort are as a rule extremely puzzling, because, no matter how definitely the organic symptoms appear, the classical train of symptoms of traumatic hysteria are almost certain to be so largely in evidence that the jury and lawyers are strongly impressed with the belief that the patient in question is "faking."

With the limited knowledge of the pathology of hysteria at our command, an accurate study of the real relations between hysteria and organic disease is difficult or impossible. With a severe trauma at the starting-point the problem is still more difficult.

In concussion of the brain certain pathological events occur. A fall or blow on the head of only moderate severity may produce the following results: A brief diminution of the blood-pressure of the part, resulting in more or less mental disturbance. The cells of the cortex of the brain do not stand being deprived of their accustomed nourishment without manifesting such symptoms as a brief perversion of memory and intellect. Memory is for the time being lost and power to recognize surrounding objects is lost or weakened. The sensory portion of the cortex responds by pain and other sensory symptoms; the motor by paralysis or symptoms of reflex excitability. Marked alterations of the cerebral circulation may occur in many conditions besides direct traumatism. Simple hyperemia is not pathological. The quality of the blood in the brain is often far more important than the quantity.

Intercranial and cerebral venous pressure vary directly with the pressure of the vena cava, and only indirectly with the aortic pressure. The volume of the blood in the brain under physiological conditions is only slightly variable. Loss of muscular control and paralysis of vasoconstrictors induced by shock or exhausting disease of any sort interferes seriously with the circulation by damaging the power of compensation, thereby permitting simple gravity to become a serious element. Under such circumstances when the subject stands in an upright posture the blood drains into the great abdominal veins, the heart empties and circulation ceases for the time being.

General shock is in addition a hyperirritation of the entire sympathetic nervous system occasioned by some sudden violent impression, causing contraction of the arterioles by stimulation of the vasomotor nerves. The character of symptoms indicates deficient vasomotor supply. The brain is made anemic, with secondary dilatation of its vessels. As hyperemia becomes excessive, the brain becomes again anemic from cessation of capillary movement and from edema. The result of compression and general contusion of the brain is the same.

After recovery from the milder degrees of shock and cerebral traumatism, a subsequent instability of cerebral nutrition due to increased susceptibility of the vasomotor centers remains with liability to anemia or hyperemia. Such persons, even after the milder degrees of traumatism, may easily remain unable to endure serious mental or physical labor, exposure to the sun, moderate alcoholic stimulation, or fatigue.

It is only very transient and slight traumatism that will thus pass by with only disturbance in the vascular and vasomotor system.

In severer grades of concussion there is in addition a jostling or displacement of the cells composing the surface of the brain. In such a condition, the patient may be unconscious of all that is around him. Or there may be a contusion of a limited surface, with local or isolated paralysis or motor convulsions, local or general, which may never recur, or which may persist as chronic epilepsy. The distention of the parenchymatous vessels already referred to may result in the formation of minute thrombi, or punctate extravasations of blood. Any attempt at absorption of these and the development of new fibrous connective tissue is apt to furnish another focus of cortical irritation which in the motor region so frequently results in epilepsy.

If the condition is to remain unimproved and chronic, the following pathological changes will be found in the cortex. The nuclei of the cells of the cortex become swollen, the cytoplasm stains diffusely with Nissl's stain; varicosities, atrophy, degeneration, hypertrophy, chromatolysis, vacuolization or complete destruction of the cell may occur; or, if there has been a hemorrhage, softening of areas of the cortex and adjacent white matter may develop. These are conditions frequently described in autopsies of epilepsy cases and in certain mental diseases.

With such pathological changes in the cortex, early evidences of mental impairment are to be expected. Or the patient may remain paralyzed in motion or special senses. Dementia associated with or independent of paralysis thus may be the result of severe injuries to the brain. Any type of mental disease may develop, either of the regular acute psychoses, such as mania or melancholia, or, as is much more commonly the case, the neuro-psychoses, such as neurasthenia or hysteria, may develop.

That tendencies exist not only on the part of the individual but of the tissues themselves to form habits must not be forgotten. This is true not only in the ordinary reflex or voluntary actions but in pathological ways. A child who has once had a convulsion is far more liable than another child to repeat it, from what might be termed newly-acquired activities of motor paths and centers, in ways the normal child might never develop. The habit of choreiform twitching in later years of childhood is easily acquired and with difficulty lost. In a suggestible individual even organic disease readily recurs. In cases of cerebral traumatism one of two conditions must exist. Either the individual has been neuropathic for years and is abnormally suggestible, in which case there is no limit to the variety of strange symptoms a slight or severe traumatism may develop; or on the other hand the individual may have been through all his previous life absolutely sound in his nervous system, and the vasomotor changes and disturbances in the cortical cells already outlined, that have taken place at the time of the accident, have changed him into a neuropath with all the suggestibility of the previous case. No more potent suggestion can be made than the set of symptoms experienced in connection with an accident. Let the suggestion be presented to the mind that these symptoms must remain permanent and a full-fledged case of traumatic hysteria is developed.

The development of a fixed idea through autosuggestion or the suggestions of friends and lawyers is made a very simple matter after the initial shock and suffering of a traumatism. Apart from such a mental origin of a set of symptoms, the possibility that some definite injury to the brain has occurred, especially to the cortex and vascular system, is more than probable. In the case recorded, the marked indentation on the left side of the head which was proved to have occurred at the time of the accident, pressure on which causes pain and even epileptic convulsions, shows definitely that serious lesion of some sort had occurred. The fit seemed to be a genuine epileptic convulsion, and was followed by a post-epileptic condition of stupor and temporary hemiplegia resembling the series of exhaustion paralyses following epileptic fits described by Clarke. Mental degeneration was at times in evidence between the fits. Then come a set of symptoms which are certainly hysteria, pure and simple. Right-sided blindness due to concentric limitation of the visual field; anesthesia of entire left side of body (the injury being also left-sided) to the median line; marked hyperesthesia of the right breast; tenderness of the skin over the area of injury to head are all of a hysterical nature.

Hystero-epilepsy may mean general hysteria with hysterical convulsions, or definite epilepsy with intercurrent hysteria, or it may be a convenient term to cover up one's ignorance as to whether hysteria or epilepsy is the proper diagnosis. From a legal standpoint this is not an unimportant question, for in the minds of the majority of lawyers as well as jurymen in this city

hysteria is still held to be synonymous with simulation.

To establish a pathology for such combined cases during life and frequently even by autopsy is a difficult problem. Admitting the presence of an exhaustion paralysis of a temporary nature following an epileptic fit, and also admitting that the condition present in my case of temporary hemiplegia and in a long series of cases reported by Clarke of the Craig Colony of various other paralyses is truly the result of exhaustion, and the question arises, Why are not these complicated symptoms which we call hysteria, so closely associated with definite epileptic attacks, to be explained, also, as fatigue symptoms in a man who was originally suffering from concussion of the brain, and secondarily from epilepsy?

One condition is common to all these traumatic cases, and that is, whether or not litigation is being carried on, they have almost invariably lost the power of working continuously at any occupation, and fatigue promptly follows any exertion.

Other theories such as a loss or perversion of the mental conception of movement, derangements of inhibition, vasomotor spasm with resulting starvation of isolated areas of the brain, have all been held at times to be the causes of hysteria. General exhaustion of the cortical centers seems a much simpler explanation.

ON EXPERIMENTAL TUBERCULOSIS OF THE SUPRARENAL CAPSULE IN RELATION TO ADDISON'S DISEASE.

PRELIMINARY REPORT OF A PATHOLOGICAL STUDY.[1]

BY BINDO DE VECCHI, M.D.,
OF BOLOGNA, ITALY.

ALTHOUGH the number of observations on the suprarenal capsule is very large and much light has been thrown upon the structure, development and functions of this organ, its pathological importance still remains obscure, especially with relation to Addison's disease. Evidently the clinical and anatomical observations are insufficient since they do not furnish a solid foundation for the various theories advanced, nor has the aid given by experiments been able to solve the question, since the results obtained have been quite diverse and at times even contradictory. The reason for this failure may lie in the fact that experiment can never duplicate the conditions that exist in human pathology.

Extirpation of the capsules, lateral or bilateral crushing, and methods of injection of these organs into healthy or decapsulated animals, have all been done over and over again, but the method of procedure, and hence the consequences, must obviously be different in Addison's disease where the morbid process induces a gradual destruction of the organs.

Since the most frequent anatomical lesion in Addison's disease is tuberculosis of the suprarenals, I have developed experimental tuberculosis in them with a view to studying its effects on the general organism, an experiment never up to the present time attempted.

The experiments were conducted on male and female rabbits, both white and colored. The injections were made on one or both sides in one or two operations. Where no complications set in and the animals recovered from the immediate effects of the operation, life continued for from three and one-half to four months. During this time the animals lost 50 per cent. in weight, there was a slight rise in temperature and a progressive diminution of the number of red cells. Loss of appetite seemed to prevail; sometimes tremor and a paresis of the hind limbs developed and the fur appeared ruffled, but never could I observe any alteration in the color of the skin or of the mucous membranes, nor was the dystrophy of the fur, noted by other observers, ever present.

The post-mortem examination never revealed any important alteration of the bowels to which death might be attributed. The capsules were in partial or complete caseation, and by killing some of the animals at varying intervals after the injection, I was able to study the histogenesis of the capsular tubercle.

Soon after the inoculation, a granulation tissue forms along the course of the wound in which epithelioid cells do not appear and in which bacilli are scarce. Later these are more numerous and epithelioid and giant cells become evident. The medulla of the organ is soon converted into a mass of caseous detritus, while the cortical substance resists destruction for a long time. Moreover there is a vigorous development of connective tissue here so that in animals left to die the cortex is divided into numerous islands outlined by thick, fibrous bands with persistence of well-preserved, probably functionating fragments of tissue.

Examinations of the solar plexus, the splanchnic nerves and the cervical and thoracic chains of sympathetic ganglia were negative. Even the ganglia nearest the suprarenals were normal. Only in one case did I find the celiac ganglion altered by the tuberculous process which had diffused itself from the capsules to the surrounding parts. In the midst of detritus, rich in bacilli, one could observe half-dissolved cellular elements filled with droplets of fat and containing deeply altered nuclei. The process did not extend to all the cells of the ganglia, but only involved the diseased side. I add that the animals lived about three months, notwithstanding this secondary change; that it showed the same asthenia, debility and paresis as the other animals operated upon by me, but there was no pigmentation of skin nor mucous membrane.

The examination of the central nervous system in all the cases gave a most interesting result. It was impossible to find any injuries of the white

[1] From the Pathological Institute of the University of Bologna (Italy); Director, Prof. G. Martinotti.

substance, but there were grave changes in the gray matter, especially in the nerve-cells themselves, in the form of an increase of the pericellular lymphatic spaces, sometimes with the presence of corpuscles probably leucocytic in character, swelling and thorny appearance of the cells, abnormal position of the nucleus with disappearance of the chromatic network and the pseudo-nucleoli, migration of the nucleolus to the outside, advanced chromatolysis of the protoplasm, a pulverized appearance of the bodies of Nissl and broken or varicose prolongations. In the posterior part of the spinal cord the nerve-cells were found entirely changed and the pericellular and perivascular spaces were filled with red cells and leucocytes. All these lesions must, in my opinion, not be attributed to changes in the sympathetic system, but to a general intoxication with tubercle toxin.

In the other organs, such as the heart, liver and kidneys, I could determine degenerative changes. No lesions were found in the lungs, alimentary tract, pituitary gland, thyroid and ovaries.

After from fifteen to twenty days a larger number of nuclear elements were found in the blood, sometimes in a state of karyokinesis. There was also a great number of leucocytic granulations. Little by little, such elements disappeared. At about the same time the bone-marrow showed the presence of many red cells in karyokinetic division and of giant cells undergoing transformation into pigmented cells. A little later, the marrow is again of normal appearance. In the spleen, in addition to slight hyperplasia of the follicles, edema of the pulp and stasis, one meets with a strong accumulation of pigment giving the iron-reaction.

From the diminution of red cells in the blood and the activity present in the bone-marrow, one may conclude that the capsules possess hemolytic properties.

I will also mention that where only one capsule was infected no signs of compensation were evident in the other.

From this short account it is clear that by tuberculizing the suprarenals a serious poisoning of the rabbits is produced which ultimately leads to their death. The circulating poison has great destructive properties as is shown by the pathological changes in the heart, liver and kidneys and the cells of the central nervous system are particularly vulnerable. These injuries explain the nervous symptoms of those suffering from Addison's disease. I did not observe any secondary changes in the sympathetic cells and in the rabbit where the celiac ganglion was partially destroyed; I encountered no symptoms not seen in the other animals. Although I have certainly succeeded in causing an intoxication in animals by this special method, I have been unable to reproduce the characteristic bronzed skin. I will elucidate my theories of Addison's disease from the voluminous literature on the subject and my own experience at another place, and will only state here in conclusion that the cause of the diseased condition produced by me lies in the gradual destruction of suprarenal substance. To this undoubted capsular insufficiency must, however, be added the tuberculous intoxication, so that we have two factors to deal with. I think I have, by my experiments, reproduced as nearly as possible the process as it goes on in the human body and while I do not believe I have entirely settled the question, it has been brought nearer to solution and an entirely new method of research has been opened.

THE PHYSICIAN AS A SOCIAL FACTOR.[1]

BY ALEXANDER ROVINSKY, M.D.,
OF NEW YORK;
CLINICAL ASSISTANT IN NEUROLOGY, VANDERBILT CLINIC, COLLEGE OF PHYSICIANS AND SURGEONS.

IT IS customary on introducing before an assemblage similar to the one I have the honor of addresing now a subject not of a strictly scientific nature, to beg the kind indulgence of the audience for lending its ear to an inquiry seemingly foreign to the chief aims and aspirations of a medical society. Following this custom, which we honor in its observance, I not only ask your attention, but hope to prove in the course of my remarks ample justification for engaging the same. It is sufficient for me to state at the outset that for the first time in the history of international medical congresses the subject for our consideration this evening was recognized as one of such prominence and importance that a whole session of the last Congress at Paris was exclusively devoted to the deliberation of propositions touching upon the mutual relations among the members of the profession and the relation of the profession as a whole to the community, in the midst of which lies its field of activity.[2]

We have occupied ourselves, almost at all our gatherings, frequently to the total exclusion or neglect of routine business, with scientific papers, communications, and clinical demonstrations. These have all been of high merit and of inestimable value to the average practitioner, whose daily laborious routine in the midst of conditions unfavorable to the cultivation of scientific research makes it difficult for him to follow even at long range the rapid progress that is being made in every branch of the great healing art.

The subject, of what is somewhat loosely denominated as medical ethics, has also claimed a goodly share of our consideration, and is destined at no distant future to absorb even more of our attention than it does now.

It occurred to me, however, that we have unduly neglected a subject of utmost importance, one that forces itself, I may say, almost daily on our notice, and which certain occurrences of recent date have made particularly prominent; I allude to the relations between the medical pro-

[1] Read before the Eastern Medical Society, May 10, 1901.
[2] Congrès International de Médecine Professionelle et d'Odontologie Médicale, publié par les soins de M. le Docteur Jules Glover, Paris, 1900.

fession and the community at large, to the rôle of the physician as a social factor. In our self-glorifications over the scientific triumphs achieved by our art and the unbounded enthusiasm that attends every recital of these triumphs, the question of the physician's standing as a factor in the community, of which, we are told, he forms so important a part, has been but lightly and superficially touched. It is only within the recollection of the younger members of the profession that such paramount issues—equally important to the community at large as well as to the profession—as the various medical abuses, the licensing of practising physicians, the hospital and dispensary defects, contract and medical insurance practice, etc., etc., were made questions important enough to be treated outside of the narrow pale of purely professional circles, and legislative aid was invoked on the principle of *salus populi*, the common weal.

Whence comes it that not a single physician's name was adjudged worthy of being inscribed on the portals of the Hall of Fame? The pages of the Colonial as well as the post-revolutionary history of the United States are replete with brilliant names of medical men who took an active part in the affairs, not only of the immediate community, but of the State and Union. To mention but a few,[3] as far back as 1647, we find, in the council of Governor-General Kieft, Dr. John de la Montague, a man of great intelligence and decision of character, a Protestant refugee from France. We find that the Colonists waged war against the Indians under the command of the indefatigable De la Montague, who later signed the treaty of peace with them. Dr. Cadwallader Colden (1688-1776) was "the most conspicuous physician of the eighteenth century." He was made first surveyer-general of the colonies by Governor Hunter; was in direct correspondence with Linnæus, wrote on yellow fever, compiled a history of the Five Indian Nations of Canada, and was a pronounced authority on botany. His intellectual capacities and attainments were great and varied, and he is spoken of by one of his biographers as "known in the scientific and literary world as a physician, botanist, astronomer, and historian."

Among the fifty-six delegates present July 4, 1776, at the signing of the Declaration of Independence, five were physicians, the most prominent of whom was Benjamin Rush, a graduate of Princeton when fifteen years old, professor of chemistry in the College of Philadelphia when twenty-four years of age. He was surgeon-general of the hospitals during the war, and for the last fourteen years of his life treasurer of the United States Mint.

We pass in rapid succession men like Latham Mitchell (1764-1831), a physician, chemist, botanist, and astronomer, the "Nestor of American Science;" David Hosack (1769-1835); John W. Draper (1811-1882), "chemist, physiologist, a many-sided man," especially known as the author of the "Intellectual Development of Europe," "The Conflict Between Religion and Science," etc.; Dr. Valentine Mott (1785-1865), who is said to have tied more arteries for the relief or cure of surgical diseases than any other surgeon; Dr. Samuel Gross (1805-1884); Dr. R. H. Gilbert, the inventor of the elevated railroad (1832-1885), and O. W. Holmes, whom American Medicine claims as much as American poetry; even if we omit men like Morton, though a dentist, Marion Sims, Bigelow and others. And out of this array of men not one was found worthy of honor! Were all these men in their individual or collective activity of less value to the nation than some of our poets, statesmen, or inventors? What truly painful spectacle to witness the inability of a profession that counts among its members many able and intelligent citizens, to cause the enforcement of the existing law against such charlatans as the Christian scientists, "that pestilential aggregation of ignorant fanaticism and unscrupulous fraud," the absurdity and dishonesty of whose methods in dealing with their dupes are evident to a mere tyro. Where are we to look for the causes of such failures? Surely not in our small numbers, for numerically we exceed by far the other liberal professions in this country, and, as compared with other countries, we have proportionately twice as many physicians as Canada, three times as many as England, four times as many as France, five times as many as Germany, and eight times as many as Russia. The average ratio is one physician to 500 inhabitants, but in some States it is as low as one to 350, or even less. In fact, so large is the number and so rapid its increase, that we are dangerously near that condition of affairs which a certain Minister of France—I believe it was Richelieu—threatened to bring about—by creating so many dukes, that it would be a shame not to be a duke, and no honor to be one.

The causes lie first of all in the indifference and apathy of a disunited profession, in the almost total absence of that *esprit de corps*, that co-operation of activity, which is the only means of establishing a firm foothold in the public estimation. The reason for this is again to be found in the remarkable heterogeneity of the elements, not to be found anywhere else in the world, that go to make up the profession here—that great difference in the education and intellectual acquirements of the rank and file of the profession which form the chief obstacle to a full understanding of the aims and aspirations of medicine, in the widest sense of the term, and for which our lamentably-defective medical institutions bear the lion's share of blame. Notwithstanding the undeniable reforms which are taking place in the education of the physicians of to-day and which tend to equalize, as far as it is possible to do so with human beings possessing free will and reasoning faculties, the intellectual standard of the graduate, we are still very far from that consummation devoutly to be wished, when an intelligent and

[3] Dr. W. L. Stowell, "The Doctor Outside of Medicine," N. Y. Med. Jour., Vol. LXIX., No. 22.

respected profession will be able to present a firm, united stand against the encroachments by the numerous quacks into public confidence. We are, indeed, far from such a millennium if, with all our reforms in medical education, justifiable complaints can be heard from well-known medical educators connected with one of the best medical institutions of the country. Thus, speaking of the various branches advantageous to him who intends to study medicine, Prof. F. S. Lee says: "Of these branches, be they few or many, to no one should be given more prominence than to the subject of English—the ability to appreciate, to speak, to write, to understand, good English. The longer becomes one's experience the more vital does this seem, and it is impressed upon one the more because of the serious lack of this ability among American youth, be they college-bred or only school-bred. The despairing cry of the college examiner, "Give me English, or give me death!" finds an answering echo in the breast of every examiner in the medical schools. The examination papers of even those who are graduates of the colleges, and even of those colleges that, recognizing the need of which I write, make the study of English especially prominent, too often teem with grammatical errors and rhetorical crudities. Even the ability to make a plain statement of facts in simple language is frequently absent, and style and literary sense are conspicuous by their rarity. In these days of the wonderful growth of the science and art of medicine, when every physician feels that he must write his book or his occasional article for the journal, and medical literature is increasing in bulk at an alarming rate, the necessity of being able to write according to the accepted canons of good literary taste is evident; and an examination of the medical literature of the day makes equally evident the fact that, in spite of many exceptions, good literary taste there is sadly wanting. This lack should not be laid at the door of the physician himself, but at the door of those who are responsible for his preliminary education. I would not attempt to say where in the course of his education, or how, the desired betterment should come in. That it should be introduced in his youth is obvious, though I sometimes feel that no more effective improvement could be made in our medical schools than the addition to their faculties of chairs of English."

Again, Prof. J. G. Curtis says: "The third deficiency—a crying one—is an insufficient knowledge of the English language, not in its higher flights, but in its plain, necessary every-day aspect. From this last deficiency, alas, not even Bachelors of Arts of the best colleges in the United States are invariably free."[4]

However, in this respect we occupy no unique position, for both our theological seminaries and our laws schools need as much mending, if not more, as the medical schools. Although neither of these professions can claim a greater aggregate of wisdom and intellect than that possessed by the medical profession as a whole, they enjoy a greater share of the public's esteem and wield, as social factors, a far greater power than the physicians in spite of the fact that the latter come in closer contact with the community and their scope of activity is wider than that of either the theologians or the lawyers, for, as some one remarked wisely, there are many who have no property to be cared for, and some with regard to whose possession of soul there may be a question, but everybody has a body which is at times liable to require skilled management to avoid suffering and death, and enable it to do its work; although some bodies, it must be confessed, are hardly worth preserving.

We live in an age of commercialism, and its blighting and corrupting influences have invaded all the ranks of the profession; for as an organic part of the social system it could not escape the tendencies of the age; this is especially true of America where the commercial instinct is so strongly developed as to impart its tincture to every phase of social life. Thus the average physician considers his profession first of all as a business venture, and, surrounded by the intense competition with his own confrères, with the hospitals, dispensaries, contract and insurance physicians, besides the numerous classes of various quacks, the scientific side of medicine is gradually lost sight of, and the great science is converted into a trade. Like the poor, we always have the "hustler" among us, the man who spares no effort, strains every energy of mind and body, for the undeviating devotion to the one aim in view—the pursuit of gain.

Alas! It is very unfortunate and detrimental to the profession as a whole, as regards its standing in the community, that this hustler does not at times hesitate to cast aside self-respect and, in his tenacity of purpose, resorts to means that are dangerously near to dishonest; and though the average man will readily acquiesce in and accept as a matter of fact the predominating influence of commercialism in any other professional pursuit, he is traditionally unwilling to acknowledge it in the physician, and looks askance at any manifestation of this tendency in his doctor.

Were we to pursue a parallel between the medical and the other two most important of the liberal professions, we could hardly attribute any special freedom from commercialism to the rank and file of our professional brethren-in-law, the members of the legal profession. The gentlemen of "the sacred calling," even though not so proficient in purely commercial matters, are nevertheless far from being free from the domination of the sensational instinct, and in them in whom decorum is next to godliness this feature is especially objectionable; the invasion of the houses of vice under the pretext of catching the beast in its lair, the discourses from the pulpit frequently laden with personalities and "invectives which might put to blush the veriest scold," the

[4] Columbia University Quarterly, March, 1901.

public indorsement of quacks and their pernicious products, are but few of the many methods adopted by the gentlemen of the cloth for springing into notoriety, into the glare of public notice. It is, however, true that,[5] "As far as the profane may judge, those disposed to doubtful paths in the pursuit of fame and fortune are but few and they have not gained the approval of the body of their fellows; but those of us who march well to the front beneath the Æsculapian banner and fight upon the frontier of professional propriety are many, and have been honored with the proverbial flattery of widespread imitation." And still can it be denied that either of the two professions of theology and law has a stronger hold on public esteem and affection than the one enjoyed by the physician? I dare say that if any question of public importance were to be propounded for solution to the representatives of the three professions, the one offered by the physician would very likely carry the least weight and importance.

To parallel the exhibition of Christian scientists in treating disease by prayer, let us imagine, in the domain of legal practice, the existence of a sect who were to decide the various differences and disputes that require resort to court or a popular vote, by what is historically known as God's judgments—those extraordinary trials by arms, single combat, by ordeal, etc., in which it was assumed that God would work a miracle to vindicate innocence and to decide what is right and what is wrong. Imagine Patrick and Jones, the famous Rice murder duet, proving their innocence in a single combat with fists and otherwise; fancy great political issues involving paramount questions touching the welfare of great commonwealths—which are but aggregations of individuals—decided in a similar manner. Fancy Mr. Roosevelt and Mr. Bryan engaged in a hand to hand combat to decide an issue on which hangs the fate of a great political party; or to come nearer home, to troubles of our own, picture to yourselves a great platform, say in Madison Square Garden, surrounded by thousands of people, on which Mr. Thomas C. Platt and Mr. Richard Croker are pounding each other most industriously—striking arguments these indeed—each whack accompanied, in the midst of incense, by loud invocations to the Almighty, from the ministers, priests and rabbis, representing all the various denominations of their respective constituents.

Now this is no laughing matter, but the incontrovertible conclusion from the chain of reasoning—alas for poor logic! What absurdities are committed in thy name!—employed by Christian scientists! What ridicule, what a howl of execration would sweep over this land if such a sect were to offer its service in a manner that is being done by the Christian scientists! Human credulity and popular ignorance are just as easily beguiled into trusting the quack and the Christian scientist, as it would be into acquiescing in the results of God's judgment; and as a matter of fact this latter procedure is synchronous in the history of civilized nations with the flourishing period of treating disease by laying on of the hands, corresponding in the history of this country to the period of Salem witchcraft, when Cotton Mather preferred this judgment to any that might be agreed to by any court of men. In many savage peoples treating disease by prayers and the reliance on the judgment of God are prevailing even into this day. Would any body of men—whether in or out of legislative halls—consider the practice of law by relying on the judgment of God in any light but that of an insane delusion, even though like Christian science, this reliance would conveniently take refuge under the cloak of religion? Whereas a similar delusion, but fraught with incomparably greater danger to the commonwealth, has been dignified into a question important enough to be brought up before various State legislatures for solution. Verily a spectacle for the gods! While ascribing to the human mind a remarkable tendency to absorb by preference whatever appears illogical, fantastical and impossible (a tendency which the great sage of Bridgeport, Conn., embodied in the trite saying, "The public likes to be humbugged"), it is not to be denied that the medical profession is to be held to a great extent responsible for the firmness with which all these humbugs take hold on the popular mind. The popularization of medical principles that can be easily made accessible to the great portion of the community is an untilled field in the medical literature of this country.

We have almost no popular works on medical subjects which would command respect of and serve as an authority to the intelligent portion of the community. Those of you who are acquainted with the medical literature of any of the European nations, and especially with the German literature, will easily comprehend how far we are outdistanced in this respect by Europe. And this virgin soil is one of the most favorable culture media for the growth and development of the various popular fallacies that can only be neutralized by the general diffusion of knowledge concerning plain every-day medical truths.

The deeper this subject is looked into the larger its scope appears and the more difficult of disentangling seem the various problems involved therein. The above is but a feeble and certainly very imperfect attempt to depict what was intended to convey to my hearers. However, cause and effect being, though necessarily incompletely, placed side by side, certain remedial agencies suggest themselves; I mean, of course, such as are within our power of application. We are unable to exert any direct influence in improving our medical schools by diminishing their number (as a curiosity let me state here that Chicago with its fourteen medical schools possesses five more than the whole of Russia, or as many as Austria, Switzerland and Denmark combined; St. Louis

[5] Dr. Charles P. Phelps, "The Medical Profession at the Close of the Nineteenth Century," N. Y. Med. Jour., Jan. 2, 1897.

is not to be outdone with her eight schools, Baltimore and Cincinnati possess six schools each, etc.), and consolidating several into one as a department of a University, thus concentrating the clinical facilities, and drawing better financial support from the University, instead of being as at present the poorest endowed of all the educational institutions in the land.

By taking a more active part in the social and political affairs of the community we shall succeed eventually in rooting out that erroneous idea, firmly implanted in the public mind, that the medical profession is always actuated by purely egoistic motives in its dealings with the community. We can influence State legislatures by either directly sending representatives or by bringing pressure to bear upon certain of them in the respective legislatures. It is perfectly astonishing how insignificant—almost non-existing—is the representation of medical men in the State legislatures and especially in Washington. Thus, in the present Fifty-sixth United States Senate there is not a single physician, although there are sixty lawyers, merchants, farmers, manufacturers, journalists, etc., etc.; while in the House of Representatives, out of a total of 357 members, there are but two—mark you, in the whole vast assembly, but two physicians—and a similar state of affairs presents itself in almost every State legislature of the land!

What wonder when questions which are considered as solved as matters of fact in Europe, such as vivisection, which are of vital importance to the pursuit of knowledge, assume here dangerous enough proportions to threaten interference with the study of medicine, and necessitate constant exertions on the part of some of the best men in the profession to counteract the pernicious influence of misguided and ignorant fanatics in the various State legislatures, as well as in the central seat of government. Small wonder, indeed, that all the efforts notwithstanding which have been put forth by large aggregations of medical men, as well as by some of the most influential individuals, the question of the establishment of a National Bureau of Health at Washington for the control and regulation of various matters relating to public hygiene etc., is as far from being realized as it ever was.

The constitutionality of State interference in the regulation of medical practice is a well-recognized fact in almost every State of the Union, and the principle involved in this sort of legislation stands settled and approved by the Supreme Court of the United States, and that of every lesser community before which it has been brought, and still not a year passes without its being assailed in all those States where the law to regulate medical practice has been introduced, after years of untiring efforts, humiliations and prostrate crawling before the politicians; and if constant vigilance were not unceasingly exerted there would be the danger of some politician slipping in certain little paragraphs that would annul the labor of years. Medical men, notwithstanding the peculiar nature of their occupation, should actively identify themselves with the various political and social movements which engage the attention of the community. The modern complicated social machinery has called into existence so many "palpitating" issues of the day, so many questions which force the attention of the intelligent and the public-spirited, that to be in closer touch with the manifold interests of the community is an absolute prerequisite for public recognition and respect, and the physician, least of all professional men, because of the very nature of his professional duties that force on his confidence matters of the most delicate nature in the individual, and those of immense importance, such as public hygiene in the widest acceptation of the term—in the community at large—the physicain can indeed, ill afford to stand at a safe distance from the burning questions of the hour, and then complain of mistrust and clamor for a share of public gratitude. The public esteem gained and the diffidence and suspicion dissipated, the many medical societies must make it one of their most important aims to create sufficient substantial political power to produce a tangible impression on the powers that rule, to be wielded *pro re nata;* the effect of the various dissensions that this may call out will be more than overbalanced by the results of the application of a united effort in a certain definite direction. Create representation in the legislative assemblies of the land and you are enabled to effectively repel the many unjust attacks for which the profession has for such a long time served as a tempting target for such as would not dare to attack in a like manner any other profession. Representation will further the establishment of that *esprit de corps* which forms the very essence of a united profession. Through representation you exert a healthy influence on whatever concerns medical matters, such as medical education, hospitals, dispensaries, unification of State boards of examination, etc., as well as public hygiene, quarantining, appointment of coroners and the like. Now, I am but too well aware of the fact that such recommendations may cause apprehension lest, if adopted, they lead to centralization and this again to so-called paternalism. Such propositions may be relegated by some to the domain of Utopia and dismissed as impracticable or premature; others may stamp them as an invasion into the personal rights of the individual, fostering attempts on the constitutional liberty of the free-born citizen, etc. Such has alway been the hue and cry of the many opponents of the State regulation of the practice of medicine; and listening to them, as I had an opportunity while attending the hearings on this subject before the Massachusetts legislature, I could not help paraphrasing in my mind the famous saying of Dr. S. Johnson about patriotism being frequently the refuge of a certain class of people.

Facts are the best arguments. The system of regulating the practice of medicine has existed for a dozen years or so and already it has resulted

in an undoubted improvement of the general standing of the profession, and if rigorously and honestly enforced it will undoubtedly become a most potent factor in the medical reform movement. Who can measure the gain that accrued to the people at large through the passage and enforcement of these measures in almost every State of the Union?

In conclusion let me repeat what I said on a similar occasion three years ago:[6] "It is high time that our State and central legislatures take a more active hand—guided by discretion and knowledge—in the amelioration of medical affairs of the land. The *laissez faire* system with its resulting individualism run amuck has about reached its highest stage of development. Decisive, intelligent interference will in the course of one or two decades revolutionize our medical affairs, improve the general standing of the physician, and elevate the profession to a position where it shall command the respect not only of the immediate community, but of the whole world. There is an undercurrent in the social life of to-day the rumblings of which are heard by every attentive ear, and which is bound sooner or later to appear on the surface; and that is the tendency to widen more and more the sphere of government and increase its power—wisely and with circumspection—as against the encroachments of individuals or corporations; for no individual however powerful, no corporation of individuals however mighty, can or will benefit the community at large, as can the State, forming a part of the people, kept in check by the people, and legislating for the people."

AN INTERESTING ACCIDENT OF STAINING.

BY J. O. COBB, M.D.,
OF FORT STANTON, NEW MEXICO;
PASSED ASSISTANT SURGEON, U. S. MARINE-HOSPITAL SERVICE.

IN the winter of 1898, while working with a mount of sputum, I used as a contrast stain methyl instead of methylene blue. In this mount I noticed a rod about three times the size of the tubercle bacillus and shaded light lilac. In other mounts the rods were constantly present in various sizes, but I paid little attention to them, thinking they were accidental air bacilli. Later at the Sanatorium at Fort Stanton, New Mexico, I showed these rods to Assistant Surgeon Ramus, who undertook to isolate them. He could never demonstrate them except with the methyl-blue stain and if this were true it was certainly interesting and such a rod, if a bacillus, should be isolated and classified.

In going into the matter thoroughly it was found to be a crystal of the stain. It was noticed that the presence of carbolic acid and heat produced beautiful crystallization and fresh preparations of the stain gave crystals much more uniform in size and much smaller than in old preparations. The crystallization seems to take place only in the presence of an albuminoid substance.

Incidentally in regard to staining sputum it is well to again call attention to the accident of staining with Sudan III. I acknowledge that it is a good stain for the tubercle bacillus, but it is unreliable. Several have called attention to the crystals found in the mount from this stain; and where we have sputum of a doubtful case Sudan III. must not be relied on, for it deposits crystals that very closely resemble the bacillus. I have in mind one case with temporary cold and expectoration which was stained with Sudan and it was thought that bacilli were present, but staining with all other methods, cultivating, and running through guinea-pigs were negative.

It is well to repeat the warnings that laboratory workers have given against the accidents of staining from old preparations of gentian-violet, methyl-violet, Rosaniline, and Sudan III. In sputum work especially must we use care with these stains. In well-marked cases where the bacilli are plentiful it makes no difference, but where the infection is recent and the diagnosis hard to make we should be prepared to exclude all sources of error and avoid any confusion by being able to say positively that we have, or have not, a tubercle bacillus in the field.

MEDICAL PROGRESS.

Fat-splitting Ferment of Stomach.—Further studies on the fat-splitting ferment normally found in the stomach have led F. VOLHARD (*Zeitschrift f. klin. Med.*, Vol. 43, No. 5 and 6) to the following results: (1) The ferment is very sensitive to the action of alkalies, but less so a glycerin extract of the mucous membrane of the stomach, while, on the other hand, it resists the influence of acid more than the extract; (2) The gastric juice contains the actual fat-splitting ferment, the mucous membrane its zymogen; (3) The decomposition of fat does not go on at a steady rate but the action is manifest only at irregular intervals; (4) The reaction is incomplete since independent of the amount of neutral fat present, and only a certain percentage is split up; (5) The law of Schietz and Borissow that the products of digestion are the equivalents of the square roots of the amount of ferment probably also holds true here; (6) In achylia gastrica the secretion of the ferment in question is also diminished; (7) Strong degrees of hyperacidity inhibit the process.

Studies in Hematology.—A very detailed and interesting article on certain structures in the blood, more particularly the granular elements found in pathologically altered erythrocytes is given by E. BLOCH (*Zeitschrift f. klin. Med.*, Vol. 43, No. 5 and 6). He finds that the living protoplasm does not readily take up the aniline dyes and that the degree of its tingeability is in direct proportion to its proximity to absolute death. The various granules and networks described in the red cells are not pre-formed structures, but are precipitated by the action of the fixing agents

and stains employed, yet they give evidence of a certain change, generally degenerative in character, which is going on in the cell. Granular degeneration of this nature is seen in many conditions, such as after experimental poisoning with phenylhydrazine, in Biermer's anemia, carcinoma, lues, tuberculosis, malaria, chronic suppuration, leucemia, rachitis and lead-poisoning. In chlorosis, pernicious anemia, diabetes mellitus, acute yellow atrophy and hepatic cirrhosis it is generally absent. Concerning malignant tumors, there need not be an extensive breaking-down of tissue to cause these granules, since they have also been seen in non-ulcerating scirrhus growths, and with reference to saturnism it seems that treatment does not cause their disappearance. In the red cells of malarial cases there also appear other granules which by some are considered the spores of plasmodia. The author believes that the true granules of degeneration are cytoplastic and not nuclear in origin for the following reasons: (1) Karyokinetic figures and granules may be abundant in one and the same red cells. Since karyokinesis represents a high type of specialization, basophylic granulation on the other hand a retrogressive process, it is obviously improbable that both processes should go on in the nucleus. (2) The relation of the granules to aniline dyes proves that they do not consist of nuclein or nucleinic substances, since, though they stain well with methylene blue, they do not take up methyl green, which is an almost specific reaction for nuclear material. (3) Granules and transitional forms between nucleated and granular cells are not found in the marrow and transitional forms do not occur in the circulating blood. The various forms of degeneration which may go on in normal or polychromatic red cells is thus summed up as follows: Considering both cyto- and karyoplasm, (*a*) *karyorrhexis or karyolysis,* (*b*) basophilic degeneration of the cytoplasm, (*c*) karyorrhexis or karyolysis or both together with cytoplastic degeneration.

Bacillal and Lysoform.—Careful experiments have been made by H. CRAMER (*Münch. med. Woch.,* Oct. 8, 1901) upon the efficiency of the two recent substitutes for carbolic acid, bacillal and lysoform, with the result that he prefers the first-mentioned of the two on account of its cheapness, lack of disagreeable odor and strength, a 1-per-cent. solution killing most organisms inside of 1 to 2 minutes, owing to the physical condition of many tuberculous sputa; however, a stronger solution and longer contact are necessary to insure comparative sterility. The author has fewer words of praise for lysoform, which, unlike bacillal, is not a creosol compound, but a solution of formaldehyde in perfumed soap. It seems to answer the purposes more of a deodorizer and cosmetic than a true antiseptic, for the staphylococcus aureus withstands a 3-per-cent. solution even after one hour.

Treatment of Tetanus.—It has been recommended to treat tetanus by repeated injections of saline solution into the organism, the theory being that the circulating toxin will thus be more readily excreted owing to change in blood-pressure. C. TONITZ (*Münch. med. Woch.,* Oct. 8, 1901) has experimentally investigated this method on animals and since he has lost several concludes that absolute success is not to be looked for in man, for the virus does not entirely circulate in the system, but in part is held combined with the tissue-elements. The tetanic symptoms are, however, rendered less acute and death may be postponed for several days.

The Asepsis of Catheterization.—To absolutely ward of infection during catheterizing, germ-free urine, urinary passages, instruments and lubricants are necessary. E. MANKIEWICZ (*Wiener klin. Rund.,* Oct. 6, 1901) states that it generally is impossible to render the urine sterile, since catheterizing to often is a procedure which must be done immediately and does not permit of preparation. Where time, however, is less pressing, much good can be done in warding off catheter fever by several doses of quinine, salol or urotropine. For the sterilizing of the urinary passages, cleansing of the meatus with benzine and sublimate and irrigation separately of urethra and bladder with saline solution or dilute silver nitrate, is recommended. A much more satisfactory subject is the sterilizing of instruments; those of good rubber or metal can readily be boiled, and it is only the woven-silk catheter which requires a special method, namely, the boiling in a strong solution of neutral ammonium sulphate. Little difficulty is generally encountered in preparing the lubricant; it is best here to use sterile vaseline in collapsible tubes.

Treatment of Anthrax.—A contribution to the therapy of this disease is made by FR. SCHULTZE (*Deut. med. Woch.,* Oct. 3, 1901). The patient under treatment was a butcher who had contracted the disease from an infected cow. His case was characterized by marked edema of face and chest, deep ulcers of the face, much difficulty in swallowing from edema of the throat, severe dyspnea, inflammation of the kidneys, and of larger bronchi, and a general condition resembling typhus. The patient made a complete recovery in four weeks, the treatment employed consisting of local applications of bichloride of mercury solution (1-1000) to the ulcers, and quinine (gr. v, q. 3 h.) and naphthalin (gr. v-x, daily) internally, for the fever and diarrhea respectively. The use of carbolic acid and iodine injections he considers harmful, especially in the face. Hot applications are of doubtful value. Incision, with cauterization, must be done early, before the surrounding tissues are infected, to be of any use. He does not believe it necessary to remove neighboring glands. On the whole, treatment should be conservative, rather than radical.

Potatoes and Diabetes.—Some time since it was announced that a diet of potatoes was favorable to the course of diabetes, producing a marked amelioration in the glucosuria, diuresis and thirst combined with a marked inprovement in the general condition of the patient. This view was first

advanced by A. MOSSE as the result of extensive observations. This investigator now reports (*Jour. Phys. et path. générale,* Sept. 15, 1901) the detailed study of two cases which confirms his opinions of the benefit to be derived from this diet. He submitted the urine and feces of these patients to extended examinations. He shows that the benefit in these cases is to be ascribed neither to defective absorption nor insufficient transformation of the carbohydrates present in the potatoes, the amount of such material voided by the intestine not being materially altered. He believes that the large amount of water introduced into the system on such a diet is an important factor. Furthermore that the hydrocarbons of potatoes are more utilizable by diabetics than has been hitherto supposed. This subject is of importance from both biological and clinical standpoints and is worthy of more extended investigation.

Treatment of Cerebral Arteriosclerosis by Inorganic "Serum."—Following the recommendation of Trunecek of Prague, a number of cases of cerebral arteriosclerosis with persistent symptoms, were treated by LÉOPOLD-LÉVI (*Gaz. Hebdom.,* Oct. 6, 1901) by subcutaneous injections of an inorganic "serum" containing sodium and potassium sulphates, sodium chloride, phosphate and carbonate in distilled water. Cases of hemiplegic character were selected in the first group, to eliminate disease of the medulla; the symptoms observed were motor, sensory and vasomotor, together with alterations in reflexes. In one case 20 injections aggregating 57 cubic centimeters of the mineral serum caused a disappearance of paresthesia of two years standing and a marked diminution of paresis of the left arm and leg; the patient was enabled to resume his occupation after six months of enforced idleness. In another case the symptoms were tingling, pain, paresis, exaggeration of reflexes involving the extremities of the left side, loss of memory, ringing in the ears, disturbance of vision, articular pains. The mineral serum injections amounted in all to 50 c.c.; a notable amelioration of the symptoms followed. The author declares that when reading the reports of Trunecek's success he was inclined to be skeptical, but the remarkable results obtained in his own cases compel him to recommend further trial of this method of treatment.

Peculiar Auditory Effects of Cinchomism.—Ordinary tinnitus aurium due to middle-ear disease never transgresses the limits of pitch from "d-1," 297 vibrations as the lowest point, to the "f-2," 704 vibrations as the highest. C. SEILER (*Med. Rec.,* Oct. 26, 1901) has found that such tinnitus has no effect upon articulation. In cases of tinnitus due to quinine, sodium salicylate etc., a much higher pitch is invariably found, ranging from 1,584 to 3,960 vibrations, being higher when salicylates were used than when quinine was the cause. Furthermore there was a well-marked interference with the articulation of certain sounds, especially those consonant sounds of very high pitch, such as "th," "s," "sh" and "z." It is well known that the hissing of steam makes it difficult for a person standing near to articulate sounds produced by about the same number of vibrations, but it is difficult to understand how this subjective tinnitus could so markedly interfere with articulation and vocalization.

Collapse of the Lung in Pneumothorax.—The question whether complete collapse of the lung does or does not occur in cases of pneumothorax, is still an open one. To answer this question, D. HELLIN (*Berl. klin. Woch.,* Oct. 7, 1901) experimented on puppies, producing in these animals a bilateral pneumothorax. He argued that the animals could be kept alive, in spite of the pneumothorax, provided the lungs were still capable of receiving a certain amount of air. It was found that even with a pleural opening as large as the tracheal circumference, the lung did not completely collapse. The author disputes the statements of König, Landois and Riedinger, who declare that in the absence of pleural adhesions bilateral pneumothorax necessarily causes immediate death. There is no clinical case on record which corresponds to this description, but the physiological and pathological conditions in such a case would be the same as in the animal experiments reported by Hellin.

Non-Parasitic Chyluria.—A number of cases of chyluria have been reported in which vigorous and repeated search failed to find parasites in either blood or urine. Autopsy in some of these showed mechanical obstruction to the lymph-flow. DR. SLOSSE (*Bulletin de la société royale des sciences méd. et nat. de Bruxelles,* July, 1901) adds a case to this list, in which as in many of the others, the ordinary day's urine was clear and contained neither fat nor albumin. If urine were allowed to accumulate in the bladder, or if the patient assumed the dorsal decubitus, chyluria resulted, while lying on the belly had no effect. This intermittence is of diagnostic importance. Chyluric urine contains finely-emulsified fat, much albumin, often fibrin, and sometimes a little blood. On standing a cream-like layer rises to the surface. The microscope shows fine, very refractive oil-globules and larger oil-globules, all animated by the Brownian movement, and perhaps a few leucocytes or strands of fibrin. The author found that the chylous urine deprived of its fat by ether, was capable of making a fine emulsion with oil, and this property he attributes to the large quantity of albumin present. There was no sugar in the urine, though such is found in lymph.

The Worsted Truss.—The simple means of treatment in medicine and surgery are alike attractive to the patient and the practitioner on account of cheapness for the former and ready availability for the latter. No truss for the retention and cure of hernia in children, says J. C. HUBBARD (*Annals of Surg.,* October, 1901), is any better than a skein of worsted. As a rule, a whole skein is too bulky and hence should be halved. It is applied by placing the loop-end

over the external abdominal ring, passing the skein across the abdomen to the left, horizontally across the back, thence forward over the right loin and groin to the ring, through the loop already there, over the internal surface of the thigh and perineum, upward over the buttock to meet the horizontal reach across the back, to which it is tied after the hernia has been replaced and the truss tightened to retain it. This truss irritates the skin only when soiled, can be washed repeatedly until its softness and elasticity are gone and is renewable at a very moderate cost. As in the case of all truss-treatment in hernias, the watchfulness of the mother is as much a factor in the result as is anything else. In about two-thirds of the cases so treated cure or improvement has resulted. In the others operation alone was efficacious.

Epidemic Cerebrospinal Meningitis.—Three types of this disease as it occurs in infancy are described by J. Lovett Morse (*Annals of Gyn. and Ped.*, Oct., 1901). The acute type is represented by a case with excessive cerebrospinal pressure and bulging fontanelle and death in four days. The autopsy showed dilated ventricles, flattened convolutions, and but little inflammatory change. Lumbar puncture, by diminishing the pressure, might have prolonged life. The symptoms of the second or *usual* type, as illustrated in a case, were retracted head, depressed fontanelle, some opisthotonos, crying when moved, waking with a sharp cry, vomiting at onset, not afterward, pupils equal, small and reacting to light, nasal discharge, and Kernig's symptom. There was no ankle-clonus, and no eruption. Later the pupils dilated widely and the fontanelle bulged, but lumbar puncture gave no relief. Death ensued in two weeks. The third or *chronic* form is exemplified in a girl of seven months, who at the onset in November would lie apathetically, the head somewhat drawn back, but at times moved from side to side. She would cry from handling. The abdomen was slightly retracted. The diplococcus intracellularis was found in the cerebrospinal fluid. Apathy became steadily more marked, a mucopurulent nasal discharge appeared, the pupils were equal, dilated and reacted feebly to light, the fontanelle was level, photophobia and lively knee-jerks were present. In April she lay quiet, unnoticing, pupils unequal, reacting slowly to light, without spasm or paralysis except slight internal strabismus. The eye-grounds were normal at repeated examinations. From the onset vomiting persisted, and for five months prior to her death on April 24th, she was fed by gavage or enemata. The loss of weight, however, was comparatively slight. After December 5th the temperature was normal, and at no time was Kernig's sign present.

Transfusion in Shock and Collapse.—Transfusion, or the rapid introduction of fluid into the vascular system, is most frequently performed in cases which are often indifferently described as cases of shock or collapse. But these two conditions differ fundamentally in their pathology and in the treatment they require, as is pointed out by A. P. Beddard (*Guy's Hospital Rep.*, Vol. LV., 1901). In both conditions the surface is cold and anemic, the respirations shallow, quick and often irregular, the pulse of low tension, frequent and small. But there is this fundamental difference between the two, that the case of collapse has lost a large quantity of fluid and the case of shock has not. In shock the veins in the splanchnic area especially lose their tone and dilate widely; the patient has bled into his own abdominal veins, and he suffers from a tremendous loss of arterial blood pressure. The indications in shock are to prevent the accumulation of blood in the abdominal veins by stimulating the vasomotor and respiratory centers; while these continue to act feebly, replace their action artificially (1) by artificial respiration; (2) by placing the patient's head lower than his feet; (3) by firmly bandaging abdomen and limbs. Meanwhile use strychnine and digitalis for cardiac stimulation, and keep the patient warm to encourage his recuperative power. The symptoms of collapse are due to excessive loss of fluid from the vascular system. In cases of severe internal hemorrhage, immediate transfusion is contraindicated as long as the bleeding vessel remains untied; when the bleeding has ceased, if the patient is dangerously collapsed he may be cautiously transfused, per rectum or subcutaneously. Collapse may develop from the continued loss of fluid by severe vomiting and diarrhea, as seen in cholera, summer diarrhea of infants, ulcerative colitis and uremia. Diagnostically it is important to remember that in cases of uncomplicated shock the specific gravity of the blood is not materially altered, but may be very slightly lowered; hemorrhage lowers the specific gravity in proportion to its extent, while injury to tissues without material hemorrhage raises it. By Hammerschlag's method (mixture of chloroform and benzol), the specific gravity of the patient's blood may be rapidly and repeatedly taken.

Asepsis of the Hands.—A surgeon is just as blameworthy if he treats a wound with germs on his hands as is the physician who prescribes a poisonous dose. A. Depage (*Bull. de la soc. royale d. sc. méd. et nat. de Bruxelles*, 1901) washes the hands in water, then in alcohol, then in sublimate solution, and finally rinses in sterilized water. Cultures on agar are taken from about the nails once each operating day. Reporting on the results for sixty-two days, he states that the surgeons and internes almost all gave cultures during the first five days, but on all the other days cultures were obtained only twice. This indicates that the surgeons quickly learned to prolong the washing as much as necessary. A nurse, however, was persistently septic for fourteen days, while medical men, who, a number of times, were asked to assist at operations, could not be made to wash sufficiently long, and always gave positive cultures.

Appendical Operations.—The surgical treatment of appendicitis will probably reach a fixed basis in time. The rules of its procedure in Germany are enunciated by REHN (*Archiv f. klin. Chir.*, 1901, B. 46, Hft. 4), as follows: (1) Severe and intense primary seizures demand immediate operation; (2) after operation all symptoms should promptly decrease; (3) recurrence of grave symptoms may demand another surgical interference; (4) repeated acute attacks always demand removal of the organ.

The X-Ray in the Diagnosis of Renal Stone; Report of Four Cases.—It seems to be true that stones containing mineral salts are more readily photographed than others, yet in two cases reported by P. THORNDIKE (*Boston Med. & Surg. Jour.*, Oct. 17, 1901) the stones were made up largely of uric acid, and in both distinct shadows were evident, while in one of them the stones were shown with considerable clearness, probably due to an admixture of calcic phosphates. In another case where there were present three small calculi of calcic oxalate with a trace of calcic phosphate, the photographer interpreted a shadow which Thorndike himself could not see; there was ample clinical indication for operation here without the X-ray photograph. In the fourth case there was some doubt about the interpretation of the plate; clinically the case called for operation and a complete exploration of the kidney demonstrated the absence of stone, the case proving to be one of hydronephrosis due probably to sagging of the kidney.

Postdiphtheritic Urticaria.—One of the objections to the use of diphtheria antitoxin is the fact that after its use an urticarial eruption occasionally occurs. J. J. WALSH (*Phila. Med. Jour.*, Oct. 12, 1901) reports a case in which, though no antitoxin was employed, urticaria developed at just about the time when the eruption would have occurred if antitoxin had been employed. The author believes that a slight urticaria or erythematous eruption occurs oftener than is reported and has been overlooked because cases untreated by antitoxin are now rare.

Sarcoma of the Uterus in Infancy.—As an instructive example of the tumors to be considered in and about the uterus in infancy, J. LORTHIOIR (*Journal de Chir.*, Aug. and Sept. 1901) reports one of sarcoma in a child three years old. In December, 1900, a small fibrous mass apparently fibroma was removed from the cervix. In March a partial vaginal hysterectomy was done by morcellement. In June a total ablation of the stump of the uterus and appendages was done by the abdominal route, for an enormous recurrence which filled the true pelvis. Death occurred by shock. The autopsy showed involvement of the mesenteric gland. Microscopically the first tumor removed was fibrous and all the tissue ablated at the other operations was more or less sarcomatous with small round-cells.

Pus in the Uterine Adnexa.—After reviewing the literature and their own experience on the subject of collections of pus in the uterine adnexa, L. MANDL and O. BURGER (*Archiv f. Gyn.*, 1901, Hft. 1, B. 64) state their estimate of the vaginal and abdominal routes of evacuation to be the following: (1) Other things being equal, they always prefer the vagina. (2) In double-sided purulent inflammation of the adnexa abdominal bilateral salpingo-oöphorectomy is now rarely done at their clinic. The operation has all the disadvantages of any laparotomy and presents no advantages in the line of permanent results. (3) Unilateral abdominal salpingo-oöphorectomy can be considered only when the disease is certainly focal on one side and the other side has surely escaped. Even then it is preferable to aspirate and determine the virulence of the pus. (4) Abdominal section is *per se* reserved for all cases which are inoperable per vaginam. (5) The vaginal route is the better in the usual run of cases when the inflammation is unilateral, bilateral and chronic. They have had the best immediate and remote results with it. (6) The advisability of a one-sided vaginal operation is only questioned when it is manfest that the uterus is normal, the opposite side intact, the pus on bacterological examination not virulent, and the abscess evidently well walled from the general peritoneal cavity. (7) Vaginal incision is, however, to be executed only under definite conditions. Some of the newer procedures with the purpose of heading the pathological processes are not to be brought into competition with it. Likewise some of the conservative operations must be recognized, but their final result in their hands does not make them first choice. (8) Abdominal incision must be reserved for those rare cases of purulent inflammation about the uterus where the pus-tumor is best opened through the abdominal walls.

Cancerous Inoculation.—Recurrence of carcinoma by pure inoculation has always been a disputed question, with the affirmative evidence although slowly yet probably surely accumulating. The following summary of what appears to have been such a case is given by R. SCHAEFFER (*Zeitschr. f. Geburtsh. u. Gyn.*, 1901, B. 45, Hft. 3) in these succinct terms: (1) The case was one of recurrence in the abdominal parieties, after at total extirpation of the uterus by the abdominal route along with the manifestly-involved large lymph-channels and nodes. The retrograde recurrence in or about the remnants of the genital appendages did not occur, although that would be the site and the manner one would reasonably expect; (2) the extirpated organs, especially the ovaries, and the recurrence in the parietes showed alike adenocarcinoma; (3) the recurrence in the abdominal wall was also the only one discoverable clinically and by microscopical examination at the time of the operation. Segments removed there showed that it was developing entirely anterior to the deep fascia having left the peritoneum entirely intact; (4) the removal of the brittle, broken-down mass appears to have been the source of direct cancerous infection.

Large Ventral Hernias.—The immediate results of the following procedure in large ventral hernias with separation of the recti have been very flattering states A. HAMMESFAHR (*Centralbl. f. Chir.,* 1901, No. 38); that the ultimate and functional results are not yet determined, because all his patients have been too recently operated on. The first step in the operation consists in removing as wide a segment of skin and the underlying fat as possible, from the symphysis pubis to the ensiform cartilage. The hernia is now treated by reduction, the sac being unopened. The rectus sheath is next opened in the middle line from end to end and the muscle bellies made free within it. The sutures, of wire, silver or aluminium-bronze, pass through the anterior sheath of the rectus and the muscle at or near their lateral limits, then between the muscle-belly and the posterior sheath toward the middle line, then forward through muscle and sheath. They then cross the middle line step-by-step in the reverse order, finally emerge at the lateral border of the sheath of the rectus. When tied the muscle bellies come together, folding slightly inward with the anterior sheath similarly folded inward lying between them. The skin is then closed in the usual manner.

A Natural Inelastic Uterine Balloon.—After suitable preparation a pig's bladder forms a cheap, universally available and, according to C. BAUMM (*Centralbl. f. Gyn.,* 1901, No. 38), entirely satisfactory obstetrical uterine balloon. The bladders can be secured in various sizes, from very small to that of the fetal head. The neck of the bladder is tied with tape or other flat medium about a small flexible tin tube, with a collar to prevent slipping. A flexible staff is passed up this tube into the bladder and by this means the balloon is introduced into the cervical canal. The preparation of the bladders is the following: Immersion for eight days in an alcoholic solution of corrosive sublimate, 1 in 180 parts. Storage after that in 96 per cent. alcohol. Ether is not advised, because after soaking in it the bladders are porous and leak. The bladders out of alcohol are stiff. Warm lysol solution prepares them for use.

Gastric Syphilis.—Truly local gastric syphilis is too often not diagnosticated, says W. S. FENWICK (*Lancet,* Sept. 28, 1901), and he reviews the symptoms in the following terms: Extremely severe nocturnal pain, infrequent hematemesis, active recurrent vomiting and obstinacy to all except antisyphilitic treatment are the cardinal features. The pain is due to the ulceration of the gumma, epigastric in site, usually provoked by solid, infrequently by any food, at times practically constant, even when the stomach is empty, at such times reaching its acme at night and radiating over the entire abdomen, and into the neck or upper and lower extremities, very commonly accompanied by syphilitic pains and tenderness in the long bones and the cranium and epigastrium, and by flatulence, acid eructations, burning in the throat and vomiting. Emesis is another conspicuous feature at first occurring only with the crises of pain, later after the secondary general gastritis is present following every meal and sometimes showing exacerbations which last many days, and depreciate the patient greatly. Through loss of nourishment, the appetite may be excessive. Cachexia or profound anemia is always secondary. Scanty neutral rather highly phosphatic urine is present. Hematemesis, the usual sign of round ulcer and necrotic cancer, is rather rare because the obliterating endarteritis prevents it. If the liver and spleen are seats of syphilitic lesions and the portal circulation is engorged, then the bleeding may be extreme in degree and persistence. Antisyphilitic treatment is well borne and rapidly relieves. The differential diagnosis is between simple, syphilitc and cancerous ulcer and tabetic crises in the stomach. Syphilitic ulcer is distinguished from simple ulcer by the excessive pain often nocturnal alike in the stomach and the long bones and by its yielding to antispecific medicies and presenting a much more profound anemia and emaciation. Gastric cancer for the relative age of the disease is still more active in depreciating the patient and may give a tumor on physical examination. Gastric crises in tabes dorsalis come at irregular intervals, can usually not be foreseen and frequently have no relation to digestive processes.

Microscopical Gynecological Diagnosis.—The detritus removed by curetting from the uterus should in case of any doubt be examined microscopically. Such a procedure will distinguish the benign from the malign conditions, as is briefly indicated by BROUHA (*Gazette de Gynecologie,* Sept. 15, 1901). Glandular endometritis presents multiplied, corkscrew-like, elongated glands instead of the straight normal glands, hence its other name hypertrophic. In hyperplastic endometritis the number of the glands is increased either by a dipping downward of the epithelium or by a bifurcation of already existing glands or by both combined. Interstitial endometritis presents augmentation of the connective tissue elements, especially near the surface of the mucosa. Sometimes while the superficial layers are in a state of interstitial inflammation, the deeper will be either hypertrophic or hyperplastic. Clinically the catarrhal cases are usually hypertrophic, the painful interstitial and the hemorrhagic are all three combined. Placental retention is shown by chorionic villi. Old cases may be difficult, because the cell arrangements have changed. Post-abortion endometritis and sometimes ectopic gestation are best shown by the correlation between large masses of dead or dying cells comprising the old decidua and similar masses of cells characteristic of pregnancy, *i.e.,* hyperplastic. Membranous dysmenorrhea, in addition to the clinical membranous cast of the endometrium, shows a high grade of interstitial hyperplasia with decrease in the number and alteration in the arrangement of the glands. Benign hydatiform moles present vari-

ous hyperplasias, myxomatous in the stroma and chiefly hypertrophic in the villi. Deciduoma malignum is a network of cells multinuclear and vacuolated. Uterine carcinoma may be found in its early stages, and any of its types, glandular, epitheliomatous, etc. Malign adenoma may also be discovered before it has gone far. Sarcoma with its predominating connective-tissue basis is also always to be looked for. Such examinations will always be of advantage to the patient and aid the physician in his choice of treatment.

Acid Intoxication of Diabetes in Its Relation to Prognosis.—While it is well known that diabetic coma is regularly associated with the excretion of large quantities of organic acids, comparatively little attention has been given to the study of the excretion of such acids during the course of diabetes previous to the coma. C. A. HERTER (*Jour. Exp. Med.*, Oct. 1, 1901) reports the examination from this standpoint of twelve cases of diabetes at different stages of the disease. Three shortly before or during coma showed large amounts of these acids in the urine. Four showed such increase several weeks before coma. In five, of which the outcome is not yet known, there was a fair increase. The estimations of organic acids present was stated in terms of oxybutyric acid because this is the preponderating organic acid present in diabetes. The amounts of glucose and organic acids present are usually parallel, but this is not always the case. The condition of diabetic coma is preceded by a period of days, weeks or months, in which there is a large excretion of these acids and patients whose urine show this condition are in danger of coma. A patient passing 30 grams of these acids daily may have sufficient energy and strength to be about and perform considerable work. A patient who has been excreting a very small amount of these acids and has gained weight may within a few months show the presence of considerable quantities of such acids and die in diabetic coma. When the urine shows only a small amount of these acids there is no immediate danger of coma, but such patients are liable to most of the complications which threaten diabetics. The amount of glucose present is not always a guide to the quantities of these acids being excreted unless the amount of glucose is large (200 grams). The acid intoxication is an important and dominant factor in the prognosis of this disease and frequent estimations of the amount of organic acids present should be made. The withdrawal of carbohydrate food frequently leads to a marked reduction in the quantity of organic acids excreted.

Cyclic Albuminuria.—In recent years considerable attention has been directed to the transitory or intermittent appearance of coagulable proteids in the urine of apparently healthy individuals. This condition has been designated as "physiological albuminuria," but much dissatisfaction has been found with this term as it is considered by many that all types of albuminuria are pathological. L. B. MENDEL and D. B. HOOKER (*Jour. Exp. Med.*, Oct. 1, 1901) have studied a case of cyclic albuminuria in a young man, twenty-four years of age. His height was 5 ft. 7 in. and his weight 126 lbs. The blood-count gave 5,200,000 reds and 5,100 whites. In making the observations the urine was collected at hourly or two-hourly intervals during the waking hours, after noting the specific gravity, volume and reaction it was filtered and heated for a half-hour or more in a boiling water-bath, a few drops of acetic acid being added when necessary to facilitiate the coagulation of the proteid. The latter were removed by filtration through paper, washed free from chlorides and dried to constant weight. During seven days' observation the average daily amount excreted was 331 milligrams. No relation was observed between the amount excreted and the diet consumed. No rise in proteid material was observed as the result of muscular exercise. A marked influence was observed as the result of posture all proteids disappearing with the maintaining of the horizontal position. No relation was observed between the volume of urine and the amount of proteid excreted. The attempt at the present time to refer physiological albuminuria so-called to attending circulatory changes in the kidney is nothing more than interesting speculation.

Experimental Data Concerning Hypodermic Injections.—This subject is of interest as applied to hypodermic medication. The general conception has been that the larger the amount of fluid employed the more effective the filtration and the better the absorption, so that it is possible to increase the effect without increasing the dose by augmenting the amount of fluid injected. S. J. MELTZER (*Jour. Exp. Med.*, Oct. 1, 1901) considers this subject from an experimental standpoint. He utilized rabbits and employed strychnine for hypodermic use on account of its characteristic reaction and the short time in which a decisive response can be obtained from its use. In the first series of investigations he endeavored to ascertain whether with a given amount the effect produced could be increased by extending the area of injection. He found that .9 milligram of strychnine distributed in injection amongst three extremities produced tonic and clonic convulsions, the first attack being twenty-seven minutes after injection. Five days later the same animal was injected with 1 milligram in one leg. No effect was produced. In another series he employed various doses of strychnine in different dilution; 8 milligram in 1 to 10,000 dilution produced no effect; 6 milligram in 1 to 200 dilution produced marked convulsions in eleven minutes. The same animal was used in both experiments, the interval being five days; .5 milligram in one-per-cent. solution kills a rabbit in a few minutes, while nearly twice as large a dose in 1 to 20,000 dilution produces no effect. This work shows that the two governing factors in the effectiveness of hypodermic medication are: (1) the area of the distribution of injection, and (2) the concentration of the injected solution.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SMITH ELY JELLIFFE, A.M., M.D., Ph.D., Editor,
No. 111 FIFTH AVENUE, NEW YORK.

Subscription Price, including postage in U. S. and Canada

SATURDAY, NOVEMBER 2, 1901.

THE BENEFIT ORDER AND THE PHYSICIAN.

THERE are, as every active practitioner knows, in almost all parts of the world certain fraternities, orders, societies and lately even companies whose sole object it is to secure medical care "by contract" and at "wholesale rates." Such bodies, too often irrespective of the quality of the medical care they secure, hire the unsuspecting new graduate and, giving him a paltry few hundred dollars a year for his services, run him to death with work which at even the minimum usual rate for individual calls will always amount to at least from three to ten times the stipend given by the society "employing" the doctor.

In Europe these orders have increased in number so rapidly and so enormously in membership that the question has taken a serious meaning as to the means by which the individual practitioner shall perform his duty to society and to his family. We have already in our columns called attention to the "strikes," pitiable because undoubtedly necessary, which have taken place among the physicians in Munich and Bamberg, because they found their fees cut to about *nineteen cents* per visit by these conditions.

In France, recently, the Société Médicale du Neuvième Arrondissement referred the question to a committee of prominent members whose report we here quote almost verbatim, as it may serve as a warning to us in this country of the possibilities in such cases, since this vampire is already present in this country, and because we believe that no right-minded physician will so demean himself as to submit to such an imposition if the facts are known.

The report of A. Gardette, Chairman (*Gazette de Gynecologie,* Aug. 15, 1901) reads: "I ask your permission to review briefly the facts which are at the bottom of the inquiry addressed to you by our confrère (M. Lacaille) for attention and advice. A society, and later, several cooperative societies, waited upon him with the request that he remit part of his fees entirely for their benefit and that of their fellow members—in other words, interference was sought by third parties in the exercise of our profession, and this was purely by intermediaries and commissioners who love to live only by the work of others. Such aim to place themselves between the physician and the patient only to take much of his income, without any benefit whatever in return, although often at the cost of his health he has to struggle to get his means of livelihood. Shall we permit these parasites to suck away our slender support? Shall we warn all those physicians, who are inclined to look solely at their own temporary good and to neglect the good of the profession in general, that they will lose more than they gain?"

Such is in brief the situation outlined by M. Lacaille. The aim of these organizations is simply to make themselves the brokers, the physicians their clerks, and the patients the wares. The committee recommends "(1) that the society send a circular to each practitioner in the arrondissement warning him of the fallacy and of the encroachments of these societies; (2) that the society recommend to each of its members a campaign against these societies through the medium of the medical press; (3) that the society send a memorial to the faculties of the medical schools requesting yearly instruction to the outgoing classes upon the aims and fundamental principles and fallacies under which these cooperative bodies operate; (4) that the society send a communication to other medical societies, which may take such action as they see fit."

This hint should be early taken and the suggestion of any connection with such bodies should never be entertained, else the realization

of the blunder will be late and withdrawal from the contracts will be found embarrassing.

INSANITY, CRIME AND THE MEDICAL EXPERT.

IN the olden days, when a man was arrested for a capital crime (in this country), little thought was expended upon the question of his mental responsibility, unless, indeed, it was plainly obvious, even to the most unobservant layman, that the criminal was likewise a raving maniac.

In recent years, the American alienist and criminologist, inspired by the researches of the Old-World investigators and desirous of extending the doctrines of psychopathology, has practically revolutionized the ancient order of things and revolutionized them to such an extent that it has really become a serious question in the minds of many people as to whether the new ideas do not threaten to defeat the ends of justice. By this we mean that it has almost come to obtain at the present day that it is difficult for a criminal to escape having insanity thrust upon him as a plea for irresponsibility, when brought face to face with justice on the charge of having committed a capital crime.

It is a well-known fact that the pursuit of science will oftentimes lead men far astray from the paths of common sense, and it has long seemed to us a timely question to ask whether the (at present) much-used plea of irresponsibility which the criminal lawyer, so-called, so tactfully handles at the instigation of the alienist, may not be only another index of the latter's scientific zeal gone wrong.

Nearly every one has enough of the milk of human kindness in his breast to be willing to concede that the taking of a human life under certain circumstances could have been none other than the work of a maniac, but it does grow wearisome to take up the paper day after day and find the plea of insanity entered as a matter of routine in murder trials. So commonplace, indeed, has such a plea become that it has for some time been the frequent theme of the paragrapher and the comic editor. We hear much from them of "The Insane Murderers' Trust" and like nonsense. Nor is this the only evil that has resulted. Only the other day, in a Massachusetts court, the jury deliberately sentenced to jail a murderer, who had been pronounced by experts both for the prosecution and for the defence a most dangerous paranoiac, on the ground that the public was tired of seeing criminals who had committed capital crimes temporarily confined in insane asylums and then allowed their full personal freedom to continue to menace the community. One learns with a sense of almost horror of such a decision and yet it is impossible not to feel that it is, in a sense, only the return of the boomerang cast by the hand of the alienist.

Curiously enough, in the very wake of this absurd decision somnambulism is set up as a defence by a Massachusetts man charged with attempt to murder his wife and a patrolman. Such a defence would be ludicrous enough in any case, in that the distinguishing feature between the merely somnambulistic state and the "twilight" condition of consciousness sometimes observed in epilepsy is that in the former there is a marked absence of all impulse to deeds of violence, so common to the latter. In the case in point it was not only shown by the Government that long existing domestic infelicities culminating in a suit for divorce were present as a motive for the shooting, but it also appeared that the defendant's somnambulistic condition was of such remarkable depth that he didn't wake up until he had attempted to shoot the patrolman who came to take him into custody. This case, by the way, also presented that stock feature which characterizes all of its kind—amnesia. The insane murderer's amnesia is really most remarkable, covering, as it usually does, every incriminating circumstance in reference to the crime and—practically nothing else. And yet in the case just quoted, the alienists offered the theory of somnambulism with all its attendant vagaries; in the full confidence of the scientific excellence of their tenets. They failed, however, to convince the court.

In the face of these facts we are reminded forcibly that medical diagnosis is, after all, a nice balance of probabilities rather than possibilities. Consequently it behooves the medical expert in cases such as we are discussing to appreciate that the public at large, outraged by the commission of a heinous crime, bears with natural impatience attempts to shield the perpetrator of such crime on the plea of irresponsibility based on purely theoretical considerations or upon wire-drawn sophistry.

It is a perfectly laudable ambition to elevate the standards of psychiatry from the almost miry stratum in which they have lain for many years to the scientific levels to which they deserve to attain, but if to accomplish this there must result a serious clash between science and sterling common sense, it appears inevitable that opprobrium will be cast upon the profession and that strict justice will not always be accorded.

THE INFLUENCE OF VIRCHOW.

THE great import of Virchow's work and teaching for modern medicine is most convincingly shown in a series of special articles contributed by eminent pathologists and physicians of many lands to a jubilee number of the *Berliner klinische Wochenschrift.* Once more that "common admiration for great and good men that draws nations together" is placed in evidence.

The anatomy and pathology of disease have been studied during the past century with greater zeal and success in France and Germany than in England, writes P. H. Pye-Smith. Many of the captains of science have passed away, but Kölliker, Pflüger and Virchow still represent the great work of Germany in histology, physiology and pathology. Many Englishmen have enjoyed the benefit of Virchow's personal instruction; most of all has his influence been exerted in England through his three great publications, the Cellular-pathologie, the Krankhafte Geschwülste, and the Gesammelte Abhandlungen. Virchow's work on tumors replaced by orderly arrangement and objective facts what was before a tangled wilderness of old superstitions and modern disconnected observations. Most far-reaching have been the effects of Virchow's insight into the relation of diseases to the three primary layers of the embryo; of his discovery of the neuroglia in the nervous centers, the cellular structure of connective tissue, the mesoblastic origin of sarcoma; of his distinction between parenchymatous and interstitial inflammatory diseases of the kidney. Scarcely less worthy of note was his masterly disentanglement of the confused facts and theories concerning pyema, phlebitis and embolism.

Chance's English translation of the Cellular-pathologie appeared in 1860 and seven American editions of the work were exhausted in a few years. The edifice of pathology, founded on Virchow's great work, became its great temple of medicine not only for America but for the world. The new era, says Abraham Jacobi, ceased to have any place for "schools" of medicine in the old sense of the term; "systems" and "rational" medicine ceased to exist. American physicians are largely indebted to Virchow for the knowledge that every crisis is necessarily secondary to a local disturbance; that while parenchymatous inflammation may represent an enhancement of nutritive or metabolic processes, it does not imply an increase of power; that both pathological anatomy and bacteriology are properly to be regarded only as aids to practical medicine. Since Virchow's advent disease processes have no longer been sought in this or that region or organ of the body, but in the cell or cell-group, and efforts have been made to adapt therapeutic measures to this view. Virchow's early popularity in the United States was increased by his appreciative and learned discussion of the sanitary achievements of the Federal army during the Civil War. The needs of the practising physician and the humanitarian were ever in his mind; in the closing chapter of his Cellular-pathologie he expresses the hope that his teachings may prove of value in the clinical practice of his pupils.

In Austria a brilliant epoch for pathological anatomy was inaugurated by the activities of Rokitansky, who struggled not only to establish the subject on a scientific basis, but to win for it its righful position as leader of practical medicine. But Rokitansky was so strongly influenced by the prevailing biological views that he was led into erroneous speculations as to the causation of morbid changes; and his humoral pathology, which regarded a change in the constitution of the blood as the forerunner of all morbid anatomical conditions, held sway until Virchow appeared with his contention that the cell is the fundamental element alike in the healthy and the diseased organism, and that all cells are developed from pre-existing cells. Virchow's pupils were called to important chairs in the great Austrian seats of learning, and the force of his personal example in scientific research was thus added to the spiritual influence of his writings. One of his most distinguished disciples, Klebs, professor of pathological anatomy at Prague, accomplished far-reaching results by applying the experimental method to the investigation of the causes of infectious diseases.

Cornil, who was elevated to the chair of pathological anatomy in Paris in 1882, succeeding Charcot, went to Berlin twenty years before, at the recommendation of Claude Bernard, to receive from Virchow his first lessons in the technic of pathological histology and in autopsy methods. Hence Cornil is one of the first to acknowledge his indebtedness to Virchow for the general trend of his work; his writings are applications of the general principles laid down in the Cellular-pathologie. Sweden, Denmark, Greece, the Netherlands, Italy and Russia, speak as with one voice of the mighty influence of Virchow upon the study and practice of medicine throughout the civilized world. *"Ses glorieuses decouvertes n'appartiennent désormais ni à la critique ni mème à l'eloge."*

METROPOLITAN NUISANCES.

The Board of Health has been making progress. It has settled the question of the tunnel nuisance in a way which can be satisfactory only to the railroad, and so leaves the subject practically unsettled. By unroofing the tunnel the gas and smoke, which were formerly almost the exclusive property of patrons of the road, will be distributed more generally and generously among the residents of Park avenue instead of being reserved entirely for those who pay fares. Electric traction in the tunnel and the millennium may be confidently expected to arrive together. The matter of negligence of the Street Cleaning Department which, aided by the work of excavating the rapid transit tunnel, has given the city more dirty and unhygienic streets than have been seen for several years, will be taken off from the shoulders of the Board of Health by the approaching election, the only apparent relief for these modern Augean stables.

There are, however, two more matters concerning the public health which might well be considered and acted upon by the Board of Health. These were both mentioned in the report of the Committee on Hygiene delivered at the annual meeting of the Medical Society of the County of New York on October 28th. They are the perennial grievance of open cars on the Metropolitan Street Railway in unseasonable and stormy weather, and the acid fumes which make a trip on the 34th street Crosstown cars an undeserved punishment, a foretaste of future possibilities. A letter was sent in the name of the County Society to the President of the Metropolitan road calling attention to the frequency with which open cars are run after the cold season has begun and during protracted storms, and asking for information. With the courtesy frequently accorded to communications which contain nothing of value financially to the recipient, this has remained unanswered. The open or so-called "pneumonia cars" are possessed of so large a carrying capacity that we may be pardoned for sharing a popular opinion that their protracted use without regard to the welfare of the public is dictated by a mercenary spirit.

The acid fumes, arising from the storage batteries of the 34th street branch, are sufficiently annoying to persons in perfect health, but to those with any predisposition to laryngeal or bronchial affections or any one suffering from such troubles, the irritating fumes are enough to bring on an acute attack.

These nuisances are commended to the attention of the Board of Health with the earnest hope that the solution of the difficulties may be satisfactory to the public rather than to the railroad.

ECHOES AND NEWS.

NEW YORK.

Execution of Czolgosz.—The assassin of President McKinley was electrocuted Tuesday morning. The autopsy was conducted by Dr. Carlos F. MacDonald, Dr. E. A. Spitzka and Dr. Gerin, the prison physician.

The skull was found to be of normal thickness. It was the unanimous agreement after microscopical examination that the brain was normal.

The following brief statement was issued:

"The autopsy was made by Dr. Edward A. Spitzka of New York, under the immediate supervision and direction of Dr. Carlos F. MacDonald of New York and Dr. John Gerin, prison physician. The autopsy occupied over three hours, and embraced a careful examination of all the bodily organs, including the brain. The examination revealed a perfectly healthy state of all the organs, including the brain. All of the physicians who attended the execution were present at the autopsy, and all concurred in the findings of the examiners."

Skene Women's Hospital to be Abandoned.—Steps were taken last week in the Kings County Supreme Court for the dissolution of the Skene Hospital for Self-Supporting Women and Children, which was one of the cherished dreams of the late Dr. Alexander J. C. Skene, the well-known Brooklyn gynecologist. The petition for the voluntary dissolution of the corporation was signed by the surviving directors, John Claflin, Hugo Hirsch, Charles A. Moore, president of the Montauk Club; Alexander E. Orr, president of the Chamber of Commerce; George Foster Peabody, Royal C. Peabody, William H. Snyder and Spencer Trask. Judge William B. Dickey ordered a hearing on the matter to-morrow. Dr. Skene was one of the best-known gynecologists in the country, and was a writer and expert upon women's cases. It had long been an idea of his that women and children should have the benefit of expert special treatment, and that many of those who most needed it were unable to pay the large fees of the competent specialist. In order to remedy this he proposed to erect a hospital in which women who had to support themselves and children could be treated without expense. He interested in the matter several of his wealthy friends, and the hospital was incorporated. Before the building which he had planned could be constructed, Dr. Skene died. The directors made up their minds that without its originator the scheme could not be put through, and the action of yesterday was the outcome of the decision.

New York State Association of Railway

Surgeons.—The eleventh annual meeting will be held in the New York Academy of Medicine, Thursday and Friday, November 14 and 15, 1901. The following program has been arranged:

Special Topic: Railway Sanitation.—Car Sanitation, by G. P. Conn, M.D., of Concord, N. H.; Transportation of Passengers Sick with Contagious Diseases, by J. N. Hurty, M.D., of Indianapolis, Ind.; Necessity of Disinfection, by M. J. Rosenau, M.D., of Washington, D. C.; Methods of Disinfecting Cars, by William H. Park, M.D., of New York; Medico-Legal Features, by L. L. Gilbert, Esq., of Pittsburg, Penn.; General Discussion, opened by Walter Wyman, M.D., of Washington, D. C., and C. O. Hunter, Esq., of Columbus, Ohio; President's Address, by W. R. Townsend, M.D., of New York City; Account and Results of a Wreck, by Henry Flood, M.D., of Elmira, N. Y.; Railway Accidents, Their Cause and Prevention from a Psychological Standpoint, by R. S. Harnden, M.D., of Waverly, N. Y.; Contusions of the Abdomen, by Walter Lathrop, M.D., of Hazleton, Penn.; Injuries of the Abdomen, by F. H. Wiggin, M.D., New York City; Contusions of the Abdomen, with Injuries of the Viscera, by L. W. Hotchkiss, M.D., New York City; When to Amputate, by H. P. Jack, M.D., of Canisteo, N. Y.

Dinner to Dr. Waldeyer.—Last Saturday over 100 members and guests of the German Medical Society of New York met to do honor to this celebrated anatomist who recently represented the German Universities at the Yale Bi-Centennial, held the week before last at New Haven. Among the invited honorary guests were Drs. W. H. Carmalt, W. H. Welch, H. M. Biggs, I. Van Gieson, James Ewing, Smith Ely Jelliffe, Frank Foster and G. F. Shrady. Dr. D. von Skal, President of the Society, acted as presiding officer; Dr. Geo. W. Jacoby as toastmaster. Drs. A. Jacobi, W. H. Welch and C. Beck were among the speakers.

A diploma of honorary membership of the "German Medical Society" was presented to Dr. Waldeyer.

PHILADELPHIA.

Presbyterian Hospital.—An addition to the facilities of the Presbyterian Hospital has been made in the shape of a new department just opened for the care of women upon whom abdominal operations have been performed. The building is the Dulles Memorial Ward to which an extension has recently been added. The department is to be under the special charge of a separate corps of nurses who are not to come in contact with other departments of the hospital.

Smallpox.—Cases for the past week numbered 59 (a decrease of 10), and deaths 10, the same as the previous week. There are now 233 cases in the city.

Estate of Dr. Da Costa.—The personal estate of the late Dr. J. M. Da Costa has been appraised at $118,000, of which $90,000 is in life insurance policies. The real estate is believed to be worth as much more.

Powerful Remedy for Smallpox.—During the present epidemic of smallpox the following from a daily paper is of interest whether or not its directions are followed. It is said to emanate from the Sisters of Charity in charge of St. Joseph's Orphan Asylum in this city, and is said to be a substitute for vaccination as well as a cure for smallpox. The prescription is: "One grain sulphate of zinc, one grain of foxglove—sometimes called digitalis; mix with two tablespoonfuls of water; when thoroughly mixed, add four ounces water. Take a teaspoonful every hour for 12 hours."

Pure Food Ruling Excites Manufacturers.—A recent ruling of Dairy and Food Commissioner Cope is causing much comment among dealers and consumers of preserved foods. The ruling is as follows: "Articles of food that can be prepared by the use of improved processes, so as to preserve them from decay or change, shall have no preservative added other than salt, syrup, sugar, saltpeter, spice, vinegar, or wood smoke." This prohibits the use of sodium benzoate which has largely been employed since the use of salicylic acid was prohibited. Manufacturers of preserved foods will probably carry the case to the Supreme Court if the Dairy Commissioner attempts to enforce the ruling.

Philadelphia Association of Retail Druggists.—At the October meeting resolutions were passed commending publicity as the best remedy for the free dispensary evil. The supplying of medicines to the outdoor poor of Philadelphia came under discussion. "The plan agreed on by the Committee and Superintendent Geary, which is to be urged upon City Councils, is that one druggist in each ward is to be selected to fill the prescriptions of the city 'Poor Physicians' for which he will be paid a salary of $200 yearly, and that the drugs used are to be supplied on requisition from the City Hospital as needed and charged to the druggist. At the end of the year the prescriptions and the requisitions for drugs will be compared. If more drugs have been requisitioned for than is shown by the prescriptions to have been used the excess will be deducted from the druggist's salary."

CHICAGO.

University of Chicago Medical Society.—A society with this name was organized October 21st by the University of Chicago. The first meeting was held at the Hull Physiological Laboratory, when Dr. J. Loeb read a paper on "The Influence of the Valency and Possibly the Electrical Charge of Ions upon their Antitoxic Effects." Dr. Albert Peacock also followed with a paper entitled "A Case of Myosis in Man." Dr. Henry H. Donaldson, head professor of neurology, was elected president of the society.

St. Gerard's Hospital Insolvent.—This hospital, which was established about a year ago,

is now declared insolvent, and a receiver has been appointed. The liabilities are $8,300, with assets of $2,400. The projectors of the hospital intended to care for as many charity patients as the patients who pay could support. For several months the charity patients exceeded in numbers those who could afford to pay, and the affairs of the hospital became worse. The income was not sufficient, and contributions practically ceased.

Public Health Matters.—The laboratory investigations of the Chicago Health Department foreshadow an increase of pneumonia and of diphtheria, the germs of these diseases being found with increasing frequency in the examinations. There is also some increase of scarlet fever apparent, especially in the northwestern portion of the city, where all the contagious diseases continue to spread. The outbreak of scarlet fever in Rogers Park has been practically suppressed, only five cases remaining at the close of last week.

Public Hospital of Moline.—The Moline Public Hospital staff has unanimously adopted resolutions asking the Mayor to remove the present board at once, and in its place appoint a board of three physicians. Also to appoint an Advisory Board, to consist of physicians who shall be made regular members of the board as soon as the law can be changed by the Legislature, making the board legally to consist of seven members, instead of three, as at present.

Changes at County Hospital.—Steps will be taken soon to establish a new form of governing body at the County Hospital. An executive cabinet is to be organized, consisting of a physician from each attending staff, a senior interne from each of the different schools of medicine, and the warden. Among the powers the Conference Committee intends to confer upon the warden is that of removing an interne for cause. Stricter rules for the assigning of patients in regular numerical order, so that partiality may not be shown to the attending staff, will also go into effect.

Chicago Medical Society.—At a meeting held October 23d, three papers on obstetrics were read. Colpeurynter in Obstetric Practice.—Dr. Jos. B. DeLee read this paper. After a brief historical résumé the following indications were noted: (1) Induction of premature labor; (2) to hasten delivery, as in eclampsia, premature detachment of placenta, heart disease, etc.; it evokes pains, softens the cervix, dilates same gently and firmly from above and makes delivery possible in a short time; (3) to prepare the parts for rapid delivery, *e. g.*, after symphysiotomy, version, etc.; (4) stenosis and rigidity of the cervix, vagina and perineum; (5) weak pains; (6) in "dry labors"; (7) in transverse presentation to keep the shoulder from wedging into the pelvis while waiting to be able to do version, and in contracted pelvis for the same purpose; (8) when the cord prolapses with the head; (9) during pregnancy to lift up a heavy uterus causing hyperemesis, and to replace a retroflexed, incarcerated uterus, filling the colpeurynter with water or mercury; (10) in placenta previa, perhaps the most valuable of all. The hemorrhage is stopped by the pressure of the placenta against the open sinuses, pains are evoked, the cervix is dilated gently and evenly, and time is given to rally the patient from collapse, to send for counsel and help. When the bag is passing through the cervix, all preparations are made for delivery, for version, etc. As soon as the bag has passed the external os, which is easily determinable, it is rapidly drawn through the vulva and further procedure instituted, which may take the form of forceps, version, another bag, or perhaps even expectancy. The writer is convinced that extended use of the colpeurynter in placenta previa will reduce maternal and fetal mortality to about almost nothing.

Anterior Vertex Presentations; Their Complications and Treatment.—Dr. Gustav Kolischer called anterior vertex presentations those presentations in which the fetal head passes through the pelvis slightly deflected, so that the anterior part of the cranium represents the lowest point of the skull. In cases of pendulous abdomen, where the fetus is the possessor of a struma, anterior vertex presentations are most likely to occur. Internal examination shows that the anterior and posterior fontanelles are on the same level, or that the large fontanelle is situated even lower than the small one. If the head has just passed the pelvic brim, the saggital suture is encountered toward the promontory, and just behind the symphysis we find an ear or the squamous suture. If the head has descended into the median plane of the pelvis, one finds the saggital suture in one of the oblique diameters, while both fontanelles are still located in the same plane. If normal rotation (occipito-anterior) has taken place in an anterior vertex presentation, the small fontanelle is found just beneath the symphysis, while the large fontanelle can be very easily reached in the perineal region. This is due to the deflection in which the fetal head is held. As to the frequency of anterior vertex presentation, comparative statistics from recent sources show that it occurs in about 8 per cent. of all head presentations. In all cases of forceps operations in anterior vertex presentation, he thinks the Walcher's posture can be used to great advantage. On account of the mento-occipital diameter, the perineum is always in great danger, and episiotomy has quite frequently been resorted to.

Occipito-Posterior Positions: Their Diagnosis and Treatment.—Dr. Charles E Paddock said that authorities differ regarding the relative frequency of the different positions of the vertex, but most agree that the occiput engages in right oblique to a large extent, about 30 per cent. of the cases being occipital right posterior, and about 4 per cent. of this 30 per cent. failing to rotate anteriorly and engaging in the hollow of the sacrum. According to
